Guidelines for the diagnosis and treatment of pulmonary hypertension

The Task Force for the Diagnosis and Treatment of Pulmonary Hypertension of the European Society of Cardiology (ESC) and the European Respiratory Society (ERS), endorsed by the International Society of Heart and Lung Transplantation (ISHLT)

Authors/Task Force Members: Nazzareno Galie (Chairperson) (Italy)*; Marius M. Hoeper (Germany); Marc Humbert (France); Adam Torbicki (Poland); Jean-Luc Vachiery (France); Joan Albert Barbera (Spain); Maurice Beigelli (Switzerland); Paul Corris (UK); Sean Gaine (Ireland); J. Simon Gibbs (UK); Miguel Angel Gomez-Sanchez (Spain); Guillaume Jondeau (France); Walter Klepetko (Austria); Christian Opitz (Germany); Andrew Peacock (UK); Lewis Rubin (USA); Michael Zellweger (Switzerland); Gerald Simonneau (France)

ESC Committee for Practice Guidelines (CPG): Alec Vahanian (Chairperson) (France); Angelo Auricchio (Switzerland); Jeroen Bax (The Netherlands); Claudio Ceconi (Italy); Veronica Dean (France); Gerasimos Filippatos (Greece); Christian Funck-Brentano (France); Richard Hobbs (UK); Peter Kearney (Ireland); Theresa McDonagh (UK); Keith McGregor (France); Bogdan A. Popescu (Romania); Zeljko Reiner (Croatia); Udo Sechtem (Germany); Per Anton Sirnes (Norway); Michal Tendera (Poland); Panos Vardas (Greece); Petr Widimsky (Czech Republic)

Document Reviewers: Udo Sechtem (CPG Review Coordinator) (Germany); Nawwar Al Attar (France); Felicita Andreotti (Italy); Michael Aschermann (Czech Republic); Riccardo Astegniano (Italy); Ray Benza (USA); Rolf Berger (The Netherlands); Damien Bonnet (France); Marion Delcroix (Belgium); Luke Howard (UK); Anastasia N Kitsiou (Greece); Irene Lang (Austria); Aldo Maggioni (Italy); Jens Erik Nielsen-Kudsk (Denmark); Myung Park (USA); Pasquale Perrone-Filardi (Italy); Suzanna Price (UK); Maria Teresa Subirana Domenech (Spain); Anton Vonk-Noordegraaf (The Netherlands); Jose Luis Zamorano (Spain)

The disclosure forms of all the authors and reviewers are available on the ESC website www.escardio.org/guidelines

The content of these European Society of Cardiology (ESC) Guidelines has been published for personal and educational use only. No commercial use is authorized. No part of the ESC Guidelines may be translated or reproduced in any form without written permission from the ESC. Permission can be obtained upon submission of a written request to Oxford University Press, the publisher of the European Heart Journal and the party authorized to handle such permissions on behalf of the ESC.

Disclaimer. The ESC Guidelines represent the views of the ESC and were arrived at after careful consideration of the available evidence at the time they were written. Health professionals are encouraged to take them fully into account when exercising their clinical judgement. The guidelines do not, however, override the individual responsibility of health professionals to make appropriate decisions in the circumstances of the individual patients, in consultation with that patient, and where appropriate and necessary the patient’s guardian or carer. It is also the health professional’s responsibility to verify the rules and regulations applicable to drugs and devices at the time of prescription.

Guidelines and Expert Consensus Documents have been issued in recent years by the European Society of Cardiology (ESC) as well as by other societies and organizations. Because of the impact on clinical practice, quality criteria for development of guidelines have been established in order to make all decisions transparent to the user. The recommendations for formulating and issuing ESC Guidelines and Expert Consensus Documents can be found on the ESC website (http://www.escardio.org/knowledge/guidelines).

In brief, experts in the field are selected and undertake a comprehensive review of the published evidence for management and/or prevention of a given condition.

Unpublished clinical trial results are not taken into account. A critical evaluation of diagnostic and therapeutic procedures is performed including assessment of the risk/benefit ratio. Estimates of expected health outcomes for larger societies are included, where data exist. The level of evidence and the strength of recommendation of particular treatment options are weighed and graded according to predefined scales, as outlined in Tables 1 and 2.

The experts of the writing panels have provided disclosure statements of all relationships they may have which might be perceived as real or potential sources of conflicts of interest. These disclosure forms are kept on file at the European Heart House, headquarters of the ESC. Any changes in conflict of interest that arise during the writing period must be notified to the ESC. The Task force report was jointly and entirely supported financially by the ESC and the European Respiratory Society (ERS) and was developed without any involvement of the industry.

The ESC Committee for Practice Guidelines (CPG) supervises and coordinates the preparation of new Guidelines and Expert Consensus Documents produced by Task Forces, expert groups, or consensus panels. The Committee is also responsible for the endorsement process of these Guidelines and Expert Consensus Documents or statements. Once the document has been finalized and approved by all the experts involved in the Task Force, it is submitted to outside specialists for review. The document is revised, and finally approved by the CPG and subsequently published. The Guidelines on the diagnosis and treatment of pulmonary hypertension have been developed by a joint Task Force of the ESC and of the ERS and the document has been approved by the ESC CPG and the ERS Scientific Committee.

After publication, dissemination of the message is of paramount importance. Pocket-sized versions and personal digital assistant (PDA)-downloadable versions are useful at the point of care. Some surveys have shown that the intended end-users are sometimes not aware of the existence of guidelines, or simply do not translate them into practice. So this is why implementation programmes for new guidelines form an important component of the dissemination of knowledge. Meetings are organised by the ESC, and directed towards its member National Societies and key opinion leaders in Europe. Implementation meetings can also be undertaken at national levels, once the guidelines have been endorsed by the ESC member societies, and translated into the national language. Implementation programmes are needed because it has been shown that the outcome of disease may be favourably influenced by the thorough application of clinical recommendations.

Preamble

Guidelines and Expert Consensus Documents summarize and evaluate all currently available evidence on a particular issue with the aim to assist physicians in selecting the best management strategies for a typical patient, suffering from a given condition, taking into account the impact on outcome, as well as the risk/benefit ratio of particular diagnostic or therapeutic means. Guidelines are no substitutes for textbooks. The legal implications of medical guidelines have been discussed previously.
Thus, the task of writing Guidelines or Expert Consensus documents covers not only the integration of the most recent research, but also the creation of educational tools and implementation programmes for the recommendations. The loop between clinical research, writing of guidelines, and implementing them into clinical practice can then only be completed if surveys and registries are performed to verify that real-life daily practice is in keeping with what is recommended in the guidelines. Such surveys and registries also make it possible to evaluate the impact of implementation of the guidelines on patient outcomes. Guidelines and recommendations should help the physicians to make decisions in their daily practice; however, the ultimate judgement regarding the care of an individual patient must be made by the physician in charge of his/her care.

1. Introduction

The Guidelines on the diagnosis and treatment of pulmonary hypertension (PH) are intended to provide the medical community with updated theoretical and practical information on the management of patients with PH. As multiple medical specialties are involved with this topic and different levels of insight may be needed by diverse physicians, these Guidelines should be considered as a compromise between heterogeneous requirements. The new features of this Guidelines document are:

- A joint Task Force of the ESC and of the ERS has developed these Guidelines. In addition, members of the International Society for Heart and Lung Transplantation and of the Association for European Paediatric Cardiology have been included.
- PH is a haemodynamic and pathophysiological state (Table 3) that can be found in multiple clinical conditions. These have been classified into six clinical groups with specific characteristics.1–6 (Table 4). To highlight the remarkable differences between these clinical groups, a comparative description of pathology, pathobiology, genetics, epidemiology, and risk factors is detailed in the first part. More practical information related to clinical presentation, diagnostic features, and treatment are described in the second part for each individual group.
- As the diagnostic strategy in patients with suspected PH is of utmost importance, a new diagnostic algorithm has been provided in the section dedicated to pulmonary arterial
hypertension (PAH, group 1). In this case the diagnosis requires the exclusion of all other groups of PH.

- PAH (Tables 4 and 5) represents the condition described more extensively due to the availability of specific treatments. Based on the publication of recent randomized controlled trials (RCTs) a new treatment algorithm with updated levels of evidence and grades of recommendation and the current approval status in different geographic areas have been provided. Definitions for the evaluation of a patient’s severity, treatment goals, and follow-up strategy have been also included. The specific characteristics of the different types of PAH including paediatric PAH have been highlighted.

- The other four main clinical groups of PH, i.e. pulmonary veno-occlusive disease (PVOD, group 1), PH due to left heart disease (group 2), PH due to lung diseases (group 3), and chronic thromboembolic pulmonary hypertension (CTEPH, group 4) have been discussed individually while the heterogeneity and rarity of the conditions included in group 5 (Table 4) prevent an appropriate description in these guidelines.

*All values measured at rest.  

*According to Table 4.  

**High CO can be present in cases of hyperkinetic conditions such as systemic-to-pulmonary shunts (only in the pulmonary circulation), anaemia, hyperthyroidism, etc.**

**CO = cardiac output; PAP = pulmonary arterial pressure; PH = pulmonary hypertension; PWP = pulmonary wedge pressure; TPG = transpulmonary pressure gradient (mean PAP – mean PWP).**

### 2. Definitions

PH has been defined as an increase in mean pulmonary arterial pressure (PAP) ≥ 25 mmHg at rest as assessed by right heart catheterization (RHC) (Tables 3 and 5). This value has been used for selecting patients in all RCTs and registries of PAH. Recent re-evaluation of available data has shown that the normal mean PAP at rest is 14 ± 3 mmHg, with an upper limit of normal of ~20 mmHg. The significance of a mean PAP between 21 and 24 mmHg is unclear. Patients presenting with PAP in this range need further evaluation in epidemiological studies.

The definition of PH on exercise as a mean PAP > 30 mmHg as assessed by RHC is not supported by published data and healthy individuals can reach much higher values. Thus no definition for PH on exercise as assessed by RHC can be provided at the present time.

According to various combinations of values of pulmonary wedge pressure (PWP), pulmonary vascular resistance (PVR), and cardiac
3. Clinical classification of pulmonary hypertension

The clinical classification of PH has gone through a series of changes since the first version was proposed in 1973 at the first international conference on primary pulmonary hypertension endorsed by the World Health Organization. The previous version of the ESC-PAH guidelines adopted the Evian-Venice classification proposed at the second and third world meetings on PAH in 1998 and 2003, respectively. In these classifications, clinical conditions with PH are classified into five groups according to pathological, pathophysiological, and therapeutic characteristics. Despite comparable elevations of PAP and PVR in the different clinical groups, the underlying mechanisms, the diagnostic approaches, and the prognostic and therapeutic implications are completely different. During the fourth World Symposium on PH held in 2008 in Dana Point, California, the consensus agreement of experts worldwide was to maintain the general philosophy and organization of the Evian-Venice classifications while amending some specific points to improve clarity and to take into account new information.

The new clinical classification (derived from the Dana Point meeting) is shown in Table 4. To avoid possible confusion among the terms PH and PAH, the specific definitions have been included in Table 5. Compared with the previous version of the clinical classification the changes are as follows:

- **Group 1**, PAH (Tables 4, 6 and 7): the term familial PAH has been replaced by heritable PAH because specific gene mutations have been identified in sporadic cases with no family history. Heritable forms of PAH include clinically sporadic idiopathic PAH (IPAH) with germline mutations (mainly of the bone morphogenetic protein receptor 2 gene as well as the activin receptor-like kinase type-1 gene or the endoglin gene) and clinical familial cases with or without identified germline mutations. This new category of heritable PAH does not mandate genetic testing in any patient with IPAH or in familial cases of PAH because this would not change the clinical management. The classification of congenital heart disease (CHD) causing PAH has been updated to include a clinical (Table 6) and an anatomical–pathophysiological version (Table 7) in order to better define each individual patient.

### Table 5 Important definitions

- Pulmonary hypertension (PH) is a haemodynamic and pathophysiological condition defined as an increase in mean pulmonary arterial pressure (PAP) ≥25 mmHg at rest as assessed by right heart catheterization (Table 3). PH can be found in multiple clinical conditions (Table 4).
- The definition of PH on exercise as a mean PAP >30 mmHg as assessed by right catheterization is not supported by published data.
- Pulmonary arterial hypertension (PAH, group 1) is a clinical condition characterized by the presence of pre-capillary PH (Table 3) in the absence of other causes of pre-capillary PH such as PH due to lung diseases, chronic thromboembolic PH, or other rare diseases (Table 4). PAH includes different forms that share a similar clinical picture and virtually identical pathological changes of the lung microcirculation (Table 4).

### Table 6 Clinical classification of congenital, systemic-to-pulmonary shunts associated with pulmonary arterial hypertension

<table>
<thead>
<tr>
<th>A. Eisenmenger’s syndrome</th>
</tr>
</thead>
<tbody>
<tr>
<td>Eisenmenger’s syndrome includes all systemic-to-pulmonary shunts due to large defects leading to a severe increase in PVR and resulting in a reversed (pulmonary-to-systemic) or bidirectional shunt. Cyanosis, erythrocytosis, and multiple organ involvement are present.</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>B. Pulmonary arterial hypertension associated with systemic-to-pulmonary shunts</th>
</tr>
</thead>
<tbody>
<tr>
<td>In these patients with moderate to large defects, the increase in PVR is mild to moderate. Systemic-to-pulmonary shunt is still largely present, and no cyanosis is present at rest.</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>C. Pulmonary arterial hypertension with small defects</th>
</tr>
</thead>
<tbody>
<tr>
<td>In cases with small defects (usually ventricular septal defects &lt;1 cm and atrial septal defects &lt;2 cm of effective diameter assessed by echocardiography) the clinical picture is very similar to idiopathic PAH.</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>D. Pulmonary arterial hypertension after corrective cardiac surgery</th>
</tr>
</thead>
<tbody>
<tr>
<td>In these cases, congenital heart disease has been corrected but PAH is either still present immediately after surgery or has recurred several months or years after surgery in the absence of significant post-operative residual congenital lesions or defects that originate as a sequela to previous surgery.</td>
</tr>
</tbody>
</table>

The size applies to adult patients.

PAH = pulmonary arterial hypertension; PVR = pulmonary vascular resistance.
characteristics with IPAH but also demonstrate a number of differences. Given the current evidence, it was felt that these conditions should be a distinct category but not completely separated from PAH, and have been designated as clinical group 1.

- Group 2, PH due to left heart disease, and group 3, PH due to lung diseases and hypoxia, are not substantially changed.
- Group 4, CTEPH: as there are no well-defined criteria to discriminate proximal from distal CTEPH obstructive lesions, it was decided to maintain only a single category of CTEPH without attempting to distinguish between proximal and distal forms.

- Group 5, PH with unclear and/or multifactorial mechanisms: this group comprises a heterogeneous collection of diseases with uncertain pathogenetic mechanisms leading to PH including haematological, systemic, metabolic, and other rare disorders.

### 4. Pathology of pulmonary hypertension

Different pathological features characterize the diverse clinical PH groups.

- Group 1, PAH: pathological lesions affect the distal pulmonary arteries (<500 μm of diameter) in particular. They are characterized by medial hypertrophy, intimal proliferative and fibrotic changes (concentric, eccentric), adventitial thickening with moderate perivascular inflammatory infiltrates, complex lesions (plexiform, dilated lesions), and thrombotic lesions. Pulmonary veins are classically unaffected.

- Group 1*: includes mainly PVOD which involves septal veins and pre-septal venules (constant involvement) with occlusive fibrotic lesions, venous muscularization, frequent capillary proliferation (patchy), pulmonary oedema, occult alveolar haemorrhage, lymphatic dilatation and lymph node enlargement (vascular transformation of the sinus), and inflammatory infiltrates. Distal pulmonary arteries are affected by medial hypertrophy, intimal fibrosis, and uncommon complex lesions.

- Group 2, PH due to left heart disease: pathological changes in this group are characterized by enlarged and thickened pulmonary veins, pulmonary capillary dilatation, interstitial oedema, alveolar haemorrhage, and lymphatic vessel and lymph node enlargement. Distal pulmonary arteries may be affected by medial hypertrophy and intimal fibrosis.

- Group 3, PH due to lung diseases and/or hypoxia: pathological changes in these cases include medial hypertrophy and intimal obstructive proliferation of the distal pulmonary arteries. A variable degree of destruction of the vascular bed in emphysematous or fibrotic areas may also be present.

- Group 4, CTEPH: pathological lesions are characterized by organized thrombi tightly attached to the pulmonary arterial medial layer in the elastic pulmonary arteries, replacing the normal intima. These may completely occlude the lumen or form different grades of stenosis, webs, and bands. Interestingly, in the non-occluded areas, a pulmonary arteriopathy indistinguishable from that of PAH (including plexiform lesions) can develop. Collateral vessels from the systemic circulation (from bronchial, costal, diaphragmatic and coronary arteries) can grow to reperfuse at least partially the areas distal to complete obstructions.

- Group 5, PH with unclear and/or multifactorial mechanisms: this group includes heterogeneous conditions with different pathological pictures for which the aetiology is unclear or multifactorial.

### 5. Pathobiology of pulmonary hypertension

Different pathobiological features characterize the diverse clinical PH groups.
• Group 1, PAH: the exact processes that initiate the pathological changes seen in PAH are still unknown even if it is recognized that PAH has a multifactorial pathobiology that involves various biochemical pathways and cell types. The increase in PVR is related to different mechanisms, including vasoconstriction, proliferative and obstructive remodelling of the pulmonary artery wall, inflammation, and thrombosis. Excessive vasoconstriction has been related to abnormal function or expression of potassium channels in the smooth muscle cells and to endothelial dysfunction. Endothelial dysfunction leads to chronically impaired production of vasodilator and antiproliferative agents such as NO and prostacyclin, along with overexpression of vasoconstrictor and proliferative substances such as thromboxane A2 and endothelin-1. Reduced plasma levels of other vasodilator and antiproliferative substances such as vasoactive intestinal peptide have also been demonstrated in patients with PAH. Many of these abnormalities both elevate vascular tone and promote vascular remodelling by proliferative changes that involve several cell types, including endothelial and smooth muscle cells as well as fibroblasts. In addition, in the adventitia there is increased production of extracellular matrix including collagen, elastin, fibronectin, and tenasin. Inflammatory cells and platelets (through the serotonin pathway) may also play a significant role in PAH. Prothrombotic abnormalities have been demonstrated in PAH patients, and thrombi are present in both the small distal pulmonary arteries and the proximal elastic pulmonary arteries.

• Group 2, PH due to left heart disease: the mechanisms responsible for the increase in PAP are multiple and include the passive backward transmission of the pressure elevation (post-capillary passive PH, Table 3). In these cases the transpulmonary pressure gradient (TPG = mean PAP minus mean PWP) and PVR are within the normal range. In other circumstances the elevation of PAP is greater than that of PWP (increased TPG) and an increase in PVR is also observed (post-capillary reactive or ‘out of proportion’ PH, Table 3). The elevation of PVR is due to an increase in the vasomotor tone of the pulmonary arteries and/or to fixed structural obstructive remodelling of the pulmonary artery resistance vessels.27 The former component of reactive PH is reversible under acute pharmacological testing while the latter, characterized by medial hypertrophy and intimal proliferation of the pulmonary arteries, does not respond to the acute challenge.12 Which factors lead to reactive (out of proportion) PH and why some patients develop the acutely reversible vasoconstrictive or the fixed obstructive components or both is poorly understood. Pathophysiological mechanisms may include vasoconstrictive reflexes arising from stretch receptors localized in the left atrium and pulmonary veins, and endothelial dysfunction of pulmonary arteries that may favour vasoconstriction and proliferation of vessel wall cells.

• Group 3, PH due to lung diseases and/or hypoxia: the pathobiological and pathophysiological mechanisms involved in this setting are multiple and include hypoxic vasoconstriction, mechanical stress of hyperinflated lungs, loss of capillaries, inflammation, and toxic effects of cigarette smoke. There are also data supporting an endothelium-derived vasoconstrictor–vasodilator imbalance.

• Group 4, CTEPH: non-resolution of acute embolic masses which later undergo fibrosis leading to mechanical obstruction of pulmonary arteries is the most important pathobiological process in CTEPH. Pulmonary thromboembolism or in situ thrombosis may be initiated or aggravated by abnormalities in either the clotting cascade, endothelial cells, or platelets, all of which interact in the coagulation process.28 Platelet abnormalities and biochemical features of a procoagulant environment within the pulmonary vasculature support a potential role for local thrombosis in initiating the disease in some patients. In most cases, it remains unclear whether thrombosis and platelet dysfunction are a cause or consequence of the disease. Inflammatory infiltrates are commonly detected in the pulmonary endarterectomy (PEA) specimens. Thrombophilia studies have shown that lupus anticoagulant may be found in ~10% of such patients, and 20% carry antiphospholipid antibodies, lupus anticoagulant, or both. A recent study has demonstrated that the plasma level of factor VIII, a protein associated with both primary and recurrent venous thromboembolism, is elevated in 39% of patients with CTEPH. No abnormalities of fibrinolysis have been identified. The obstructive lesions observed in the distal pulmonary arteries of non-obstructed areas (virtually identical to those observed in PAH) may be related to a variety of factors, such as shear stress, pressure, inflammation, and the release of cytokines and vasculotrophic mediators.

• Group 5, PH with unclear and/or multifactorial mechanisms: the pathobiology in this group is unclear or multifactorial.

6. Genetics, epidemiology, and risk factors of pulmonary hypertension

Comparative epidemiological data on the prevalence of the different groups of PH are not available. In a survey performed in an echocardiography laboratory,29 the prevalence of PH (defined as a PA systolic pressure >40 mmHg) among 4579 patients was 10.5%. Among the 483 cases with PH 78.7% had left heart disease (group 2), 9.7% had lung diseases and hypoxia (group 3), 4.2% had PAH (group 1), 0.6% had CTEPH (group 4), and in 6.8% it was not possible to define a diagnosis.

• Group 1, PAH: recent registries have described the epidemiology of PAH.3,4 The lowest estimates of the prevalence of PAH and IPAH are 15 cases and 5.9 cases/million adult population, respectively. The lowest estimate of PAH incidence is 2.4 cases/million adult population/year. Recent data from Scotland and other countries have confirmed that PAH prevalence is in the range 15–50 subjects per million population in Europe.8 In the French registry, 39.2% of patients had IPAH and 3.9% had family history of PAH. In the subgroup of APAH, 15.3% had connective tissue diseases (CTDs; mainly systemic sclerosis), 11.3% had CHD, 10.4% had portal hypertension, 9.5% had anorexigen-associated PAH and 6.2% had human immunodeficiency virus (HIV) infection.
PAH may occur in different settings depending on associated clinical conditions.1 IPAH corresponds to sporadic disease, without any familial history of PAH or known triggering factor. When PAH occurs in a familial context, germline mutations in the bone morphogenetic protein receptor 2 gene are detected in at least 70% of cases.14,15 Mutations of this gene can also be detected in 11–40% of apparently sporadic cases, thus representing the major genetic predisposing factor for PAH.30 The bone morphogenetic protein receptor 2 gene encodes a type 2 receptor for bone morphogenetic proteins, which belong to the transforming growth factor-β superfamily. Among several biological functions, these polypeptides are involved in the control of vascular cell proliferation. Mutations of other receptors for these substances, such as activin receptor-like kinase 1 and endoglin, have been identified mostly in PAH patients with a personal or family history of hereditary haemorrhagic telangiectasia (Osler–Weber–Rendu syndrome).31 A number of risk factors for the development of PAH have been identified and are defined as any factor or condition that is suspected to play a predisposing or facilitating role in the development of the disease. Risk factors were classified as definite, likely, possible, or unlikely based on the strength of their association with PH and their probable causal role.1 A definite association is acknowledged in the case of an epidemic such as occurred with appetite suppressants in the 1960s or if large, multicentre epidemiological studies demonstrated an association between the clinical condition or drug and PAH. A likely association is acknowledged if a single centre case–control study or multiple case series demonstrated an association. A possible association can be suspected, for example, for drugs with similar mechanisms of action to those in the definite or likely category but which have not been studied yet, such as drugs used to treat attention deficit disorder. Lastly, an unlikely association is defined as one in which a suspected factor has been studied in epidemiological studies and an association with PAH has not been demonstrated. Definite clinical associations are listed among APAH conditions (Table 4) while the risk level of different drugs and toxins is listed in Table 8.

- Group 2, PH due to left heart disease: even if constitutional factors may play a role in the development of PH in this group, no specific genetic linkages have been identified.12 The prevalence of PH in patients with chronic heart failure increases with the progression of functional class impairment. Up to 60% of patients with severe left ventricular (LV) systolic dysfunction and up to 70% of patients with isolated LV diastolic dysfunction may present with PH.32 In left-sided valvular diseases, the prevalence of PH increases with the severity of the defect and of the symptoms. PH can be found in virtually all patients with severe symptomatic mitral valve disease and in up to 65% of those with symptomatic aortic stenosis.10,12,33

- Group 3, PH due to lung diseases and/or hypoxaemia: one study has shown that serotonin gene polymorphism appears to determine the severity of PH in hypoxaemic patients with chronic obstructive pulmonary disease (COPD).34 Based on published series, the incidence of significant PH in hypoxic COPD patients with at least one previous hospitalization for exacerbation of respiratory failure is 20%. In advanced COPD, PH is highly prevalent (>50%).35,36 Although in general it is of only mild severity. In interstitial lung disease, the prevalence of PH is between 32 and 39%.37 The combination of lung fibrosis with emphysema is associated with a higher prevalence of PH.38

- Group 4, CTEPH: no specific genetic mutations have been linked to the development of CTEPH. Even if more recent papers suggest that the prevalence of CTEPH is up to 3.8% in survivors of acute pulmonary embolism,39 most experts believe that the true incidence of CTEPH after acute pulmonary embolism is 0.5–2%. CTEPH can be found in patients without any previous clinical episode of acute pulmonary embolism or deep venous thrombosis (up to 50% in different series).40

- Group 5, PH with unclear and/or multifactorial mechanisms: the heterogeneity of this group prevents an appropriate description of genetics, epidemiology and risk factors in these guidelines.

PAH = pulmonary arterial hypertension.

### 7. Pulmonary arterial hypertension (group 1)

PAH (see Table 5 for definition) represents the type of PH in which the most important advances in the understanding and treatment have been achieved in the past decade. It is also the group in which PH is the ‘core’ of the clinical problems and may be treated by specific drug therapy.

PAH comprises apparently heterogeneous conditions (Table 4) that share comparable clinical and haemodynamic pictures and virtually identical pathological changes of the lung microcirculation. Even if many pathobiological mechanisms have been identified in the cells and tissues of patients with PAH, the exact interactions between them in the initiation and progression of the pathological processes are not well understood. The consequent increase in PVR leads to right ventricular (RV) overload, hypertrophy, and dilatation, and eventually to RV failure and death. The importance of the progression of RV failure on the outcome of IPAH patients is confirmed by the prognostic impact of right atrial pressure, cardiac index (CI), and PAP,8 the three main parameters of RV pump function. The inadequate adaptation of myocardial
contractility seems to be one of the primary events in the progression of heart failure in a chronically overloaded RV. Changes in the adrenergic pathways of RV myocytes leading to reduced contractility have been shown in IPAH patients. Afterload mismatch remains the leading determinant of heart failure in patients with PAH and CTEPH because its removal, as follows successful PEA or lung transplantation, leads almost invariably to sustained recovery of RV function. The haemodynamic changes and the prognosis of patients with PAH are related to the complex pathophysiological interactions between the rate of progression (or regression) of the obstructive changes in the pulmonary microcirculation and the response of the overloaded RV, which may also be influenced by genetic determinants.

7.1 Diagnosis

The evaluation process of a patient with suspected PH requires a series of investigations intended to confirm the diagnosis, clarify the clinical group of PH and the specific aetiology within the PAH group, and evaluate the functional and haemodynamic impairment. After the description of each examination, an integrated diagnostic algorithm is shown (Figure 1). Since PAH, and particularly IPAH, is a diagnosis of exclusion, this algorithm may be useful as a starting point in any case of suspected PH.

7.1.1 Clinical presentation

The symptoms of PAH are non-specific and include breathlessness, fatigue, weakness, angina, syncope, and abdominal distension. Symptoms at rest are reported only in very advanced cases. The physical signs of PAH include left parasternal lift, an accentuated pulmonary component of second heart sound, a pansystolic murmur of tricuspid regurgitation, a diastolic murmur of pulmonary insufficiency, and an RV third sound. Jugular vein distension, hepatomegaly, peripheral oedema, ascites, and cool extremities characterize patients in a more advanced state. Lung sounds are usually normal. The examination may also provide clues as to the cause of PH. Telangiectasia, digital ulceration, and sclerodactyly are seen in scleroderma, while inspiratory crackles may point towards interstitial lung disease. The stigmata of liver disease such as spider naevi, testicular atrophy, and palmar erythema should be considered. If digital clubbing is encountered in IPAH, an alternative diagnosis such as CHD or PVOD should be sought.

7.1.2 Electrocardiogram

The ECG may provide suggestive or supportive evidence of PH by demonstrating RV hypertrophy and strain, and right atrial dilatation. RV hypertrophy on ECG is present in 87% and right axis deviation in 79% of patients with IPAH. The absence of these findings on ECG may provide suggestive or supportive evidence of PH by exclusion. RV hypertrophy on ECG is present in 87% and right axis deviation in 79% of patients with IPAH. The simplified Bernoulli equation describes the relationship of tricuspid regurgitation velocity and the peak pressure gradient of tricuspid regurgitation = 4 × (tricuspid regurgitation velocity). This equation allows for estimation of PA systolic pressure taking into account right atrial pressure: PA systolic pressure = tricuspid regurgitation pressure gradient + estimated right atrial pressure. Right atrial pressure can be estimated based on the diameter and respiratory variation of the inferior vena cava although often a fixed value of 5 or 10 mmHg is assumed. When peak tricuspid regurgitation velocity is difficult to measure (trivial/mild tricuspid regurgitation), use of contrast echocardiography (e.g. agitated saline) significantly increases the Doppler signal, allowing proper measurement of peak tricuspid regurgitation velocity. Also, potential systolic gradients between the RV and PA should be considered. Theoretically, calculation of mean PAP from PA systolic pressure is possible (mean PAP = 0.61 × PA systolic pressure + 2 mmHg). This could allow the use of Doppler measurements, applying an accepted definition of PH as mean PAP ≥25 mmHg. Unfortunately, despite the
Strong correlation of the tricuspid regurgitation velocity and tricuspid regurgitation pressure gradient, Doppler-derived pressure estimation may be inaccurate in the individual patient. In patients with severe tricuspid regurgitation use of the simplified form of the Bernoulli equation may lead to underestimation of PA systolic pressure. Also overestimations by >10 mmHg for PA systolic pressure are common. Therefore, PH cannot be reliably defined by a cut-off value of Doppler-derived PA systolic pressure. Consequently, estimation of PAP based on Doppler transthoracic echocardiography measurements is not suitable for screening for mild, asymptomatic PH.
Contrast CT angiography of the PA is helpful in determining whether there is evidence of surgically accessible CTEPH. It can delineate the typical angiographic findings in CTEPH such as complete obstruction, bands and webs, and intimal irregularities as accurately and reliably as digital subtraction angiography. With this technique, collaterals from bronchial arteries can be identified.

Traditional pulmonary angiography is still required in many centres for the work-up of CTEPH to identify patients who may benefit from PEA. Angiography can be performed safely by experienced staff in patients with severe PH using modern contrast media and selective injections. Angiography may also be useful in the evaluation of possible vasculitis or pulmonary arteriovenous malformations.

### 7.1.8 Cardiac magnetic resonance imaging
Cardiac magnetic resonance imaging provides a direct evaluation of RV size, morphology, and function, and allows non-invasive assessment of blood flow including stroke volume, CO, distensibility of PA, and RV mass. Cardiac magnetic resonance data may be used to evaluate right heart haemodynamics particularly for follow-up purposes. A decreased stroke volume, an increased RV end-diastolic volume, and a decreased LV end-diastolic volume measured at baseline are associated with a poor prognosis. Among the triad of prognostic signs, increased RV end-diastolic volume may be the most appropriate marker of progressive RV failure in the follow-up.

### 7.1.9 Blood tests and immunology
Routine biochemistry, haematology, and thyroid function tests are required in all patients, as well as a number of other essential blood tests. Serological testing is important to detect underlying CTD, HIV, and hepatitis. Up to 40% of patients with IPAH have elevated anti-nuclear antibodies, usually in low titre (1:80). Systemic sclerosis is the most important CTD to exclude because this condition has a high prevalence of PAH. Anti-centromere antibodies are typically positive in limited scleroderma as are other anti-nuclear antibodies including dsDNA, anti-Ro, U3-RNP, B23, Th/To, and U1-RNP. In the diffuse variety of scleroderma, U3-RNP is typically positive. In individuals with systemic lupus erythematosus, anti-cardiolipin antibodies may be found. Thrombophilia screening including anti-phospholipid antibodies, lupus anticoagulant, and anti-cardiolipin antibodies should be performed in CTEPH. HIV testing is mandatory. Up to 2% of individuals with liver disease will manifest PAH and therefore liver function tests and hepatitis serology should be examined if clinical abnormalities are noted. Thyroid disease is commonly seen in PAH and should always be considered, especially if abrupt changes in the clinical course occur.

### 7.1.10 Abdominal ultrasound scan
Liver cirrhosis and/or portal hypertension can be reliably excluded by the use of abdominal ultrasound. The use of contrast agents and the addition of a colour-Doppler examination may improve the accuracy of the diagnosis. Portal hypertension can be confirmed by the detection of an increased gradient between free and occluded (wedge) hepatic vein pressure at the time of RHC.

### 7.1.11 Right heart catheterization and vasoreactivity
RHC is required to confirm the diagnosis of PAH, to assess the severity of the haemodynamic impairment, and to test the vasoreactivity of the pulmonary circulation. When performed at experienced centres, RHC procedures have low morbidity (1.1%) and mortality (0.055%) rates. The following variables must be recorded during RHC: PAP (systolic, diastolic, and mean), right atrial pressure, PWP, and RV pressure. CO must be measured in triplicate preferably by thermodilution or by the Fick method, if oxygen consumption is assessed. The Fick method is mandatory in the presence of a systemic-to-pulmonary shunt. Superior vena cava, PA, and systemic arterial blood oxygen saturations should also be determined. These measurements are needed for the calculation of PVR. Adequate recording of PWP is required for the differential diagnosis of PH due to left heart disease. In rare cases, left heart catheterization may be required for direct assessment of LV end-diastolic pressure. A PWP > 15 mmHg excludes the diagnosis of pre-capillary PAH. One of the most challenging differential diagnoses of PAH is heart failure with normal LV ejection fraction and diastolic dysfunction (see also section 9.1). In this population, PWP may be mildly elevated or at the higher end of the normal range at rest. Exercise haemodynamics or volume challenge can show a disproportionate increase in PWP, although the relevance of this finding remains to be established. Coronary angiography may be required in the case of the presence of risk factors for coronary artery diseases and angina or in case of listing for double lung transplantation or PEA in patients with CTEPH.

In PAH, vasoreactivity testing should be performed at the time of diagnostic RHC to identify patients who may benefit from long-term therapy with calcium channel blockers (CCBs) (see also section 7.3.3). Acute vasodilator challenge should only be performed with short-acting, safe, and easy to administer drugs with no or limited systemic effects. Currently the agent most used in acute testing is NO (Table 9) based on previous experience and intravenous (i.v.) epoprostenol or i.v. adenosine may also be used as an alternative (but with a risk of systemic vasodilator effects) (Table 10).

Inhaled iloprost and oral sildenafil may be associated with significant vasodilator effects. Their role in the prediction of the response to CCB therapy has not yet been demonstrated. Due to the risk of potentially life-threatening complications, the use of CCBs given orally or i.v. as an acute test is discouraged. A positive acute response (positive acute responder) is defined as a reduction of mean PAP ≥ 10 mmHg to reach an absolute value of mean PAP ≤ 40 mmHg with an increased or unchanged CO. Only ~10% of patients with IPAH will meet these criteria. Positive acute responders are most likely to show a sustained response to long-term treatment with high doses of CCBs and they are the only patients that can safely be treated with this type of therapy. About half of IPAH-positive acute responders are also positive long-term responders to CCBs and only in these cases is the continuation of a CCB as a single treatment warranted. The usefulness of acute vasoreactivity tests and long-term treatment with CCBs in patients with other PAH types, such as heritable PAH, CTD, and HIV patients is less clear than in IPAH. Nevertheless, experts recommend performing acute vasoreactivity studies in these patients and to look for a long-term response to CCBs in those in which the test is positive. No data are available on the usefulness of long-term CCB therapy in patients with PH associated
with CHD and therefore the value of performing a vasoreactivity test in this setting is controversial. Acute vasoreactivity studies to identify patients with a long-term favourable response to CCBs is not recommended in clinical groups 2, 3, 4, and 5 (Table 4).

Recommendations for RHC and vasoreactivity test are summarized in the Table 11.

7.1.12 Diagnostic algorithm

The diagnostic algorithm is shown in Figure 1: the diagnostic process starts with the identification of the more common clinical groups of PH (group 2—left heart disease and group 3—lung diseases), then distinguishes group 4—CTEPH and finally makes the rarer conditions in group 5.

PAH should be considered in the differential diagnosis of exertional dyspnoea, syncope, angina, and/or progressive limitation of exercise capacity, particularly in patients without apparent risk factors, symptoms or signs of common cardiovascular and respiratory disorders. Special awareness should be directed towards patients with associated conditions and/or risk factors for development of PAH, such as family history, CTD, CHD, HIV infection, portal hypertension, haemolytic anaemia, or a history of intake of drugs and toxins known to induce PAH (Table 8). In everyday clinical practice such awareness may be low. More often PH is found unexpectedly on transthoracic echocardiography requested for another indication.

If non-invasive assessment is compatible with PH, clinical history, symptoms, signs, ECG, chest radiograph, transthoracic echocardiogram, pulmonary function tests (including nocturnal oximetry, if required), and high-resolution CT of the chest are requested to identify the presence of group 2—left heart disease or group 3—lung diseases. If these are not found or if PH seems ‘out of proportion’ to their severity, less common causes of PH should be looked for. Ventilation/perfusion lung scan should be considered. If a ventilation/perfusion scan shows multiple segmental perfusion defects, a diagnosis of group 4—CTEPH should be suspected. The final diagnosis of CTEPH (and the assessment of suitability for PEA) will require CT pulmonary angiography, RHC, and selective pulmonary angiography. The CT scan may also show signs suggestive of group 1—PVOD. If a ventilation/perfusion scan is normal or shows only subsegmental ‘patchy’ perfusion defects, a tentative diagnosis of group 1—PAH or the rarer conditions of group 5 is made. In Table 12 the further

*aClass of recommendation.

*bLevel of evidence.
management according to the likelihood of PAH is given including indications for RHC. Additional specific diagnostic tests including haematology, biochemistry, immunology, serology, and ultrasonography will allow the final diagnosis to be refined. Open or thorascopic lung biopsy entails substantial risk of morbidity and mortality. Because of the low likelihood of altering the diagnosis and treatment, routine biopsy is discouraged in PAH patients.

Recommendations for diagnostic strategy are summarized in the Table 13.

### 7.2 Evaluation of severity

The evaluation of severity of patients with PAH takes place between the diagnostic process and the therapeutic decision making. The clinical assessment of the patient has a pivotal role in the choice of the initial treatment, the evaluation of the response to therapy, and the possible escalation of therapy if needed.

#### 7.2.1 Clinical, echocardiographic, and haemodynamic parameters

Both clinical and haemodynamic assessments yield important prognostic information which may guide clinical management. These data have been derived from cohorts of patients and may not accurately reflect the prognosis of individuals. Prognosis is significantly affected by the aetiology of PAH.

Despite large interobserver variation in the measurement, WHO functional class (WHO-FC) (Table 14) remains a powerful predictor of survival. In untreated patients with IPAH or heritable PAH, historical data showed a median survival of 6 months for WHO-FC IV, 2.5 years for WHO-FC III, and 6 years for WHO-FC I and II. Extreme patients (age(≤14 years or >65 years), falling exercise capacity, syncope, haemoptysis, and signs of RV failure also carry a poor prognosis in IPAH.

Echocardiography generates many indices, and those with the best prognostic value identified by multivariate analysis are pericardial effusion, indexed right atrium area, LV eccentricity index, and the RV Doppler index. Estimated systolic PAP derived from tricuspid regurgitant jet velocity is not prognostic. The tricuspid annular plane systolic excursion (TAPSE) has been reported to be of prognostic value.

Resting haemodynamics measured at RHC predict prognosis. These include PA oxygen saturation, right atrial pressure, CO, PVR, and a marked vasoactivity response. PAP is also prognostic but less reliable as it may fall towards the end stage of the disease as the RV fails. Some studies suggest that reduced arterial O₂ saturation, low systolic blood pressure, and increased heart rate carry a worse prognosis.
Right atrial pressure, CI, and mean PAP have been incorporated in a formula to predict prognosis. It is unclear whether this formula is applicable to current clinical practice.

### 7.2.2 Exercise capacity

For objective assessment of exercise capacity, the 6-minute walking test (6MWT) and cardiopulmonary exercise testing are commonly used in patients with PAH.

The 6MWT is technically simple, inexpensive, reproducible, and well standardized. In addition to distance walked, dyspnoea on exertion (Borg scale) and finger O$_2$ saturation are recorded. Walking distances <332 m$^7^8$ or <250 m$^7^9$ and O$_2$ desaturation >10%$^8^0$ indicate impaired prognosis in PAH. With respect to treatment effects, absolute values >380 m following 3 months of i.v. epoprostenol correlated with improved survival in IPAH patients while the increase from baseline did not. The increase in 6MWT distance has remained the primary endpoint in most pivotal PAH RCTs. The test is not sufficiently validated in PAH subgroups and is influenced by (but not corrected for) body weight, gender, height, age, and patient motivation.$^7^7$

With cardiopulmonary exercise testing gas exchange and ventilation are continuously recorded throughout incremental exercise. In PAH, O$_2$ uptake at the anaerobic threshold and peak exercise are reduced in relation to disease severity, as are peak work rate, peak heart rate, O$_2$ pulse, and ventilatory efficiency.$^8^1$ Following multivariate analysis of clinical, haemodynamic, and exercise parameters peak O$_2$ uptake (<10.4 ml O$_2$/kg/min) and peak systolic arterial pressure during exercise (<120 mmHg) independently predicted a worse prognosis in IPAH patients.$^7^5$

While the results of both methods do correlate in PAH, cardiopulmonary exercise testing failed to confirm improvements observed with 6MWT in RCTs.$^8^2$,$^8^3$ Although lack of standardization and insufficient expertise in performing cardiopulmonary exercise testing were identified as the main reasons explaining this discrepancy,$^8^1$ the 6MWT remains until now the only Food and Drug Administration- and European Agency for the Evaluation of Medicinal Products-accepted exercise endpoint for studies evaluating treatment effects in PAH. Despite detailed recommendations,$^8^4$,$^8^5$ a generally accepted standardization of cardiopulmonary exercise testing with respect to data acquisition and analysis in PAH is lacking.

### 7.2.3 Biochemical markers

Biochemical markers emerged within the last decade as an attractive non-invasive tool for assessment and monitoring of RV dysfunction in patients with PH.

Serum uric acid is a marker of impaired oxidative metabolism of ischaemic peripheral tissue. High uric acid levels were found to relate to poor survival in patients with IPAH.$^8^6$ However, allopurinol is often prescribed to patients with PAH, and hyperuricaemia and diuretics influence its plasma levels, impairing the value of clinical monitoring based on uric acid levels.

Atrial natriuretic peptide and brain natriuretic peptide (BNP) share similar physiological properties. Both induce vasodilatation and natriuresis and are released from myocardium in response to wall stress. Interest in the clinical application of natriuretic peptides in monitoring RV failure due to chronic PH has focused on BNP.

The final step of BNP synthesis consists of a high molecular weight precursor, proBNP cleaved into biologically inactive N-terminal segment (NT-proBNP) and the proper low molecular weight BNP. NT-proBNP has a longer half-life and a better stability both in circulating blood and after sampling. RV failure is the main cause of death in PAH, and BNP/NT-proBNP levels reflect the severity of RV dysfunction. Nagaya et al.$^8^7$ showed that the baseline median value of BNP (150 pg/mL) distinguished patients with a good or bad prognosis. In 49 out of 60 patients, BNP measurement was repeated after 3 months of targeted therapy and again the supramedian level (>180 pg/mL) was related to worse long-term outcome. Plasma BNP significantly decreased in survivors but increased in non-survivors despite treatment. In a trial involving 68 patients with PAH associated with scleroderma, NT-proBNP below a median of 553 pg/mL was related to better 6-month and 1-year survival.$^8^8$ Using receiver operating characteristic (ROC) analysis, an NT-proBNP cut-off point at 1400 pg/mL was predictive of a 3-year outcome in 55 patients with severe pre-capillary PH.$^8^9$ Serum NT-proBNP below 1400 pg/mL seemed particularly useful for identification of patients with good prognosis, who would not need escalation of treatment in the immediate future, and this has been independently confirmed.$^9^0$ Larger outcome trials are still required to verify the suggested cut-off levels for NT-proBNP.

Increases in NT-proBNP plasma levels on follow-up have been associated with worse prognosis.$^8^8$ Several recent trials assessing new drugs in PAH or CTEPH reported a significant decrease in NT-proBNP in the actively treated vs. placebo patients.

Elevated plasma levels of cardiac troponin T and troponin I are established specific markers of myocardial damage and are prognostic indicators in acute coronary syndromes and acute pulmonary embolism. Elevated cardiac troponin T was an independent predictor of fatal outcome during 2-year follow-up in a single trial on 51 patients with PAH and five with CTEPH.$^9^1$ In some
patients cardiac troponin T disappeared from plasma either temporarily or permanently after introduction of treatment. The value of monitoring of the cardiac troponin T level in patients with PH still requires confirmation in future studies. Other biomarkers are currently under investigation.\textsuperscript{92,93}

In conclusion, several circulating biomarkers convey prognostic information in patients with PAH, but their value in everyday clinical practice is still not established.

BNP/NT-proBNP plasma levels should be recommended for initial risk stratification and may be considered for monitoring the effects of treatment, in view of their prognostic implications. Low and stable or decreasing BNP/NT-proBNP may be a useful marker of successful disease control in PAH.

### 7.2.4 Comprehensive prognostic evaluation

Regular evaluation of patients with PAH should focus on variables with established prognostic importance as outlined above. Treatment decisions should be based on parameters that reflect symptoms and exercise capacity and that are relevant in terms of predicting outcome. Not all parameters obtained repeatedly in PAH patients are equally well suited to assess disease severity. For example, PAP is measured on a regular basis, either by RHC or by echocardiography. The magnitude of the PAP correlates poorly with symptoms and outcome as it is determined not only by the degree of PVR increase but also by the performance of the RV. Thus, the PAP alone should not be used for therapeutic decision making. Table 15 lists several parameters of known prognostic importance that are widely used as follow-up tools. Not all parameters need to be assessed at every visit (Table 16), but in order to obtain a clear picture it is important to look at a panel of data derived from clinical evaluation, exercise tests, biochemical markers, and echocardiographic and haemodynamic assessments. It is crucial not to rely just on a single parameter as several assessments may provide divergent results. In addition, no clear-cut thresholds for any single parameters can be identified to separate patients with good prognosis from those with a poor one. In Table 15, patients with better or worse prognosis are separated by an intermediate group for which prognostication is more difficult. In these cases, additional factors not included in Table 15 should be considered such as age, aetiology, and co-morbidities.

### 7.2.5 Definition of patient status

Based on the clinical, non-invasive and invasive findings the clinical condition of a patient can be defined as stable and satisfactory, stable but not satisfactory, unstable and deteriorating:

**Stable and satisfactory**—Patients in this condition should fulfil the majority of the findings listed in the ‘better prognosis’ column of Table 15. In particular, the patient is characterized by absence of clinical signs of RV failure,\textsuperscript{79} stable WHO-FC I or II without syncope, a 6 min walk distance >500 m,\textsuperscript{79,95} depending on the individual patient, a peak VO\textsubscript{2} >15 mL/min/kg,\textsuperscript{75,96} normal or near-normal BNP/NT-proBNP plasma levels,\textsuperscript{87,89} no pericardial effusion,\textsuperscript{71} TAPSE >2.0 cm,\textsuperscript{74} right atrial pressure <8 mmHg, and a CI ≥2.5 L/min/m\textsuperscript{2}.\textsuperscript{8,79,95,97,98}

**Stable and not satisfactory**—This is a patient who although stable has not achieved the status which patient and treating physician would consider desirable. Some of the limits described above for a stable and satisfactory condition and included in the first column of Table 15 are not fulfilled. These patients require re-evaluation and consideration for additional or different treatment following full assessment in the referral centre (see specific paragraph for definition).

\textsuperscript{a}Depending on age.
\textsuperscript{b}TAPSE and pericardial effusion have been selected because they can be measured in the majority of the patients.

\textsuperscript{1}BNP = brain natriuretic peptide; CI = cardiac index; 6MWT = 6-minute walking test; RAP = right atrial pressure; TAPSE = tricuspid annular plane systolic excursion; WHO-FC = WHO functional class.
Unstable and deteriorating—Patients in this condition fulfill the majority of the findings listed in the ‘worse prognosis’ column of Table 15. In particular, the patient is characterized by evidence of progression of RV failure symptoms and signs, worsening WHO-FC, i.e., from II to III or from III to IV, a 6 min walk distance of <300 m,79,95 a peak VO2 <12 mL/min/kg,75 rising BNP/NT-proBNP plasma levels,87,89 evidence of pericardial effusion,71 TAPSE <1.5 cm,74 right atrial pressure >15 mmHg and rising, or a CI that is ≤2.0 L/min/m² and falling.8,79,95,97,98 Clinical warning signs are increasing oedema and/or the need to escalate diuretic therapy, new onset or increasing frequency/severity of angina which can be a sign of deteriorating RV function, and the onset or increasing frequency of syncope which is often a grim prognostic sign and requires immediate attention as it heralds low output heart failure. Supraventricular arrhythmias may be seen in this condition and contribute to clinical deterioration.

7.2.6 Treatment goals and follow-up strategy (see also section 7.3.7 and Table 22)

Treatment goals for PAH patients which may be considered are those listed in the ‘stable and satisfactory definition’ and in the ‘better prognosis’ column of Table 15. Target values and treatment goals should be adjusted to the individual patient. For example, a 6MWT >400 m is usually considered acceptable in PAH patients. Younger patients are often capable of walking 500 m or more despite the presence of severe PH and RV dysfunction. In these patients, additional exercise testing with cardiopulmonary exercise test and/or RHC is particularly useful in order to obtain a more reliable assessment of RV function. Peak VO₂, O₂ pulse, peak systolic blood pressure during exercise, and the minute ventilation/carbon dioxide production slope (ventilator efficacy) provide important information about RV function during exercise.75,96 Biomarkers, echocardiography, and RHC are useful additional tools to decide whether or not the patient can be considered stable. Suggested follow-up strategies for patients with PAH are reported in Table 16.

There is no universally accepted consensus about when and how often to perform follow-up RHC. Some, but not all, expert centres perform RHC regularly, for example once a year. Some centres use RHC whenever a change in treatment is considered, while others regularly perform RHC 3–6 months after new treatments have been instituted to ensure that haemodynamics are in the desired range. In terms of prognostic importance, the most relevant haemodynamic variables are cardiac output, RAP and mixed-venous oxygen saturation, i.e., those variables that reflect RV function. Recommendations for the use of RHC in PAH patients are provided in Table 11.

Recommendations for evaluation of severity and follow-up are summarized in Table 17.
7.3 Therapy
In the past few years, treatment of PAH has undergone an extraordinary evolution, which has led to the current approval by regulatory agencies of eight drugs with different routes of administration. Additional drugs are expected in the near future. Modern drug therapy leads to a significant improvement in patients’ symptomatic status and a slower rate of clinical deterioration. In addition, a meta-analysis performed on 23 RCTs in PAH patients (published prior to October 2008) reports a 43% decrease in mortality and a 61% reduction in hospitalizations in patients treated with specific drug therapies vs. patients randomized to placebo.99 These results, achieved after an average treatment period of 13.3 weeks, support the efficacy of the currently approved PAH treatments. Despite this finding, PAH remains a chronic disease without a cure. In addition, the medical and interventional treatments for more advanced cases are still invasive and prone to significant side effects.

The therapy of PAH patients cannot be considered as a mere prescription of drugs but is characterized by a complex strategy which includes the evaluation of severity, supportive and general measures, the assessment of vasoreactivity, the estimation of efficacy, and combination of different drugs plus interventions. In any of these steps, the knowledge and experience of the responsible physician are critical to optimize the available resources.

7.3.1 General measures
Patients with PAH require sensible advice about general activities of daily living and need to adapt to the uncertainty associated with a serious chronic life-threatening disease. The diagnosis usually confers a degree of social isolation.100 Encouraging patients and their family members to join patient support groups can have positive effects on coping, confidence, and outlook.

Physical activity and supervised rehabilitation
Patients should be encouraged to be active within symptom limits. Mild breathlessness is acceptable but patients should avoid exercise that leads to severe breathlessness, exertional dizziness, or chest pain. A recent study has shown the value of a training programme in improving exercise performance.101 Patients should therefore avoid excessive physical activity that leads to distressing symptoms, but when physically deconditioned may undertake supervised exercise rehabilitation.

One recent study has demonstrated an improvement in exercise capacity in patients with PAH who took part in a training programme.101 More data are required before appropriate recommendations can be made. There is growing evidence supporting loss of peripheral muscle mass in patients with advanced PAH, and this may be corrected by a defined rehabilitation programme.

Pregnancy, birth control, and post-menopausal hormonal therapy
There is consistency from the WHO, existing guidelines, and the Expert Consensus Document of the ESC102 that pregnancy is associated with 30–50% mortality in patients with PAH,103 and as a consequence PAH is a contra-indication to pregnancy. There is less consensus relating to the most appropriate methods of birth control. Barrier contraceptive methods are safe for the patient but with an unpredictable effect. Progesterone-only preparations such as medroxyprogesterone acetate and etonogestrel are effective approaches to contraception and avoid potential issues of oestrogens as those included in the old generation mini-pill.104 It should be remembered that the endothelin receptor antagonist (ERA) bosentan may reduce the efficacy of oral contraceptive agents. The Mirena coil is also effective but rarely leads to a vasovagal reaction when inserted, which may be poorly tolerated in severe PAH.104 A combination of two methods may also be utilized. The patient who becomes pregnant should be informed of the high risk of pregnancy, and termination of pregnancy discussed. Those patients who choose to continue pregnancy should be treated with disease-targeted therapies, planned elective delivery, and effective close collaboration between obstetricians and the PAH team.105,106

It is not clear if the use of hormonal therapy in post-menopausal women with PAH is advisable or not. It may be considered in cases of intolerable menopausal symptoms in conjunction with oral anticoagulation.

Travel
There are no studies using flight simulation to determine the need for supplemental O2 during prolonged flights in patients with PAH. The known physiological effects of hypoxia suggest that in-flight O2 administration should be considered for patients in WHO-FC III and IV and those with arterial blood O2 pressure consistently <8 kPa (60 mmHg). A flow rate of 2 L/min will raise inspired O2 pressure to values seen at sea level. Similarly, such patients should avoid going to altitudes above 1500–2000 m without supplemental O2. Patients should be advised to travel with written information about their PAH and be advised how to contact local PH clinics in close proximity to where they are travelling.

Psychosocial support
Many PAH patients develop anxiety and depression leading to impairment in quality of life. Timely referral to a psychiatrist or psychologist should be made when appropriate. Information on the severity of the disease is available from many non-professional sources, and an important role of the PAH multidisciplinary team is to support patients with accurate and up to date information. Patient support groups may also play an important role in this area, and patients should be advised to join such groups.

Infection prevention
Patients with PAH are susceptible to developing pneumonia, which is the cause of death in 7% of cases.44 Whilst there are no controlled trials, it is recommended to vaccinate against influenza and pneumococcal pneumonia.

Elective surgery
Elective surgery is expected to have an increased risk in patients with PAH. It is not clear as to which form of anaesthesia is preferable but epidural is probably better tolerated than general anaesthesia. Patients usually maintained on oral therapy may require temporary conversion to i.v. or nebulized treatment until they are able both to swallow and to absorb drugs taken orally.
Diuretics

Decompensated right heart failure leads to fluid retention, raised central venous pressure, hepatic congestion, ascites, and peripheral oedema. Although there are no RCTs of diuretics in PAH, clinical experience shows clear symptomatic benefit in fluid-overloaded patients treated with this therapy. The choice and dose of diuretic therapy may be left to the PAH physician. The addition of aldosterone antagonists should also be considered. It is important to monitor renal function and blood biochemistry in patients to avoid hypokalaemia and the effects of decreased intravascular volume leading to pre-renal failure.

Oxygen

Although O$_2$ administration has been demonstrated to reduce the PVR in patients with PAH there are no randomized data to suggest that long-term O$_2$ therapy is beneficial. Most patients with PAH except those with CHD and pulmonary-to-systemic shunts have minor degrees of arterial hypoxaemia at rest unless they have a patent foramen ovale. There are data showing that nocturnal O$_2$ therapy does not modify the natural history of advanced Eisenmenger’s syndrome. Guidance may be based on evidence in patients with COPD; when arterial blood O$_2$ pressure is consistently less than 8 kPa (60 mmHg) patients are advised to take O$_2$ to achieve a arterial blood O$_2$ pressure of >8 kPa for at least 15 h/day. Ambulatory O$_2$ may be considered when there is evidence of symptomatic benefit and correctable desaturation on exercise.

Digoxin

Digoxin has been shown to improve cardiac output acutely in IPAH although its efficacy is unknown when administered chronically. It may be given to slow ventricular rate in patients with PAH who develop atrial tachyarrhythmias.

Recommendations for general measures are summarized in the Table 18.

**7.3.2 Supportive therapy**

*Oral anticoagulants*

There is a high prevalence of vascular thrombotic lesions at post-mortem in patients with IPAH. Abnormalities in coagulation and fibrinolytic pathways have also been reported. This, together with the possible presence of non-specific risk factors for venous thromboembolism, including heart failure and immobility, represents the rationale for oral anticoagulation in PAH. Evidence in favour of oral anticoagulation is confined to patients with IPAH, heritable PAH, and PAH due to anorexigen; it is generally retrospective and based on single centre experience. The potential benefits of oral anticoagulation should be weighed against the risks in patients with other forms of PAH especially when there is an increased risk of bleeding such as portopulmonary hypertension with severe oesophageal varices. Further research into the role of oral anticoagulation and PAH is encouraged. Advice regarding the target international normalized ratio (INR) in patients with IPAH varies from 1.5—2.5 in most centres of North America to 2.0—3.0 in European centres. Generally, patients with PAH receiving therapy with long-term i.v. prostanoids are anticoagulated in the absence of contra-indications due in part to the additional risk of catheter-associated thrombosis.

*Diuretics*

Decompensated right heart failure leads to fluid retention, raised central venous pressure, hepatic congestion, ascites, and peripheral oedema. Although there are no RCTs of diuretics in PAH, clinical experience shows clear symptomatic benefit in fluid-overloaded patients treated with this therapy. The choice and dose of diuretic therapy may be left to the PAH physician. The addition of aldosterone antagonists should also be considered. It is important to monitor renal function and blood biochemistry in patients to avoid hypokalaemia and the effects of decreased intravascular volume leading to pre-renal failure.

**Diuretic treatment is indicated in PAH patients with signs of RV failure and fluid retention** | I | C |

**Continuous long-term O$_2$ therapy is indicated in PAH patients when arterial blood O$_2$ pressure is consistently less than 8 kPa (60 mmHg)** | I | C |

**Oral anticoagulant treatment should be considered in patients with IPAH, heritable PAH, and PAH due to use of anorexigen** | Ila | C |

**Oral anticoagulant treatment may be considered in patients with APAH** | Iib | C |

**Digoxin may be considered in patients with PAH who develop atrial tachyarrhythmias to slow ventricular rate** | Iib | C |

$^c$See also recommendations for PAH associated with congenital cardiac shunts (Table 25).
increasingly recognized that only a small number of patients with IPAH who demonstrate a favourable response to acute vasodilator testing at the time of RHC (see also section 7.1.11) do well with CCBs. The CCBs that have been predominantly used in reported studies are nifedipine, diltiazem, and amlodipine, with particular emphasis on the first two. The choice of CCB is based upon the patient’s heart rate at baseline, with a relative bradycardia favouring nifedipine and amlodipine and a relative tachycardia favouring diltiazem. The daily doses of these drugs that have shown efficacy in IPAH are relatively high, 120–240 mg for nifedipine, 240–720 mg for diltiazem, and up to 20 mg for amlodipine. It is advisable to start with a low dose, e.g. 30 mg of slow release nifedipine twice a day, 60 mg of diltiazem three times a day (t.i.d.), or 2.5 mg of amlodipine once a day and increase cautiously and progressively to the maximum tolerated dose. Limiting factors for dose increase are usually systemic hypotension and lower limb peripheral oedema. Patients with IPAH who meet the criteria for a positive vasodilator response and are treated with a CCB should be followed closely for both safety and efficacy with an initial reassessment after 3–4 months of therapy including RHC.

If the patient does not show an adequate response (Figure 2), defined as being in WHO-FC I or II and with a marked haemodynamic improvement, additional PAH therapy should be instituted. Patients who have not undergone a vasoreactivity study or those with a negative study should not be started on a CCB because of potential severe side effects (e.g. hypotension, syncope, and RV failure).

Vasodilator responsiveness does not appear to predict a favourable long-term response to CCB therapy in patients with PAH in the setting of CTD, and high dose CCBs are often not well tolerated in such patients. Prostanoids

Prostacyclin is produced predominantly by endothelial cells and induces potent vasodilatation of all vascular beds. This compound is the most potent endogenous inhibitor of platelet aggregation and it also appears to have both cytoprotective and antiproliferative activities. Dysregulation of the prostacyclin metabolic pathways has been shown in patients with PAH as assessed by reduction of prostacyclin synthase expression in the pulmonary arteries and of prostacyclin urinary metabolites. The clinical use of prostacyclin in patients with PAH has been extended by the synthesis of stable analogues that possess different pharmacokinetic properties but share qualitatively similar pharmacodynamic effects.

Epoprostenol. Epoprostenol (synthetic prostacyclin) is available as a stable freeze-dried preparation that needs to be dissolved in alkaline buffer for i.v. infusion. Epoprostenol has a short half-life (3–5 min) and is stable at room temperature for only 8 h. This explains why it needs to be administered continuously by means of an infusion pump and a permanent tunnelled catheter. The efficacy of continuous i.v. administration of epoprostenol has been tested in three unblinded RCTs in patients with IPAH and in those with PAH associated with the scleroderma spectrum of diseases. Epoprostenol improves symptoms, exercise capacity, and haemodynamics in both clinical conditions, and is the only treatment shown to improve survival in IPAH in a randomized study. Long-term persistence of efficacy has also been shown in IPAH, as well as in other APAH conditions and in non operable CTEPH. Treatment with epoprostenol is initiated at a dose of 2–4 ng/kg/min, with doses increasing at a rate limited by side effects (flushing, headache, diarrhoea, leg pain). The optimal dose varies between individual patients, ranging in the majority between 20 and 40 ng/kg/min.

Serious adverse events related to the delivery system include pump malfunction, local site infection, catheter obstruction, and sepsis. Guidelines for the prevention of central venous catheter bloodstream infections have recently been proposed. Abrupt interruption of the epoprostenol infusion should be avoided as, in some patients, this may lead to a rebound PH with symptomatic deterioration and even death.

Ilprost. Ilprost is a chemically stable prostacyclin analogue available for i.v., oral, and aerosol administration. Inhaled therapy for PAH is an attractive concept that has the theoretical advantage of being selective for the pulmonary circulation. Inhaled iloprost has been evaluated in one RCT (AIR) in which daily repetitive iloprost inhalations (6–9 times, 2.5–5 μg/inhalation, median 30 μg daily) were compared with placebo inhalation in patients with PAH and CTEPH. The study showed an increase in exercise capacity and improvement in symptoms, PVR, and clinical events in enrolled patients. A second RCT (STEP) on 60 patients already treated with bosentan has shown increase in exercise capacity (P <0.051) in the subjects randomized to the addition of inhaled iloprost in comparison with placebo. Overall, inhaled iloprost was well tolerated, with flushing and jaw pain being the most frequent side effects. Continuous i.v. administration of iloprost appears to be as effective as epoprostenol in a small series of patients with PAH and CTEPH. The effects of oral iloprost have not been assessed in PAH.

Tadalafil. Tadalafil is a selective PDE5 inhibitor that is selectively active on the vasculature in a TAD-dependent manner and constricts the systemic circulation. Although the role of PDE5 in the pulmonary vasculature is not completely elucidated, a PDE5 inhibitor is a reasonable treatment choice in IPAH. Tadalafil has been tested in a small pulmonary vasodilator study in IPAH patients with WHO-FC I or II and was well tolerated.

Tadalafil has shown efficacy in IPAH and other forms of PAH in two RCTs, and it has been recently approved for treatment of PAH in the USA. Tadalafil reduces PVR more than placebo in both IPAH and PAH associated with systemic sclerosis. The use of tadalafil is associated with a significant decrease in PVR and a concomitant increase in exercise capacity. However, the long-term beneficial effect of tadalafil in patients with PAH is not yet known.

Treprostinil. Treprostinil is a tricyclic benzidine analogue of epoprostenol, with sufficient chemical stability to be administered at ambient temperature. These characteristics allow administration of the compound by the i.v. as well as the s.c. route. The s.c. administration of treprostinil can be accomplished by a microinfusion pump and a small subcutaneous catheter. The effects of treprostinil in PAH were studied in the largest worldwide RCT performed in this condition, and showed improvements in exercise capacity, haemodynamics, and symptoms. The greatest exercise improvement was observed in patients who were more compromised at baseline and in subjects who could tolerate the upper quartile dose (>13.8 ng/kg/min). Infusion site pain was the most common adverse effect of treprostinil, leading to discontinuation of the treatment in 8% of cases on active drug and limiting dose increase in an additional proportion of patients. Among the 15% of patients who continued to receive s.c. treprostinil alone, survival appears to be improved. In another long-term, open-label study, a sustained improvement in exercise capacity and symptoms with s.c. treprostinil was reported in patients with IPAH or CTEPH, with a mean follow-up of 26 months. Treatment with s.c. treprostinil is initiated at a dose of 1–2 ng/kg/min, with doses increasing at a rate limited by side effects (local site pain, flushing, headache). The optimal dose varies between individual patients, ranging in the majority between 20 and 80 ng/kg/min. Treprostinil has been recently approved in the USA also for i.v. use in patients with PAH: the effects appear to be comparable with those of epoprostenol but at a dose which is between two and...
three times higher. It is, however, more convenient for the patient because the reservoir can be changed every 48 h as compared with 12 h with epoprostenol. A phase III RCT (TRIUMPH) of inhaled treprostinil in patients on background therapy with either the ERA bosentan or the phosphodiesterase type-5 inhibitor sildenafil was recently completed, and preliminary data show improvements in exercise capacity. Oral treprostinil is currently being evaluated in RCTs in PAH.

Figure 2 Evidence-based treatment algorithm for pulmonary arterial hypertension patients (for group 1 patients only). *To maintain arterial blood O$_2$ pressure $\geq$ 8 kPa (60 mmHg). †Under regulatory review in the European Union. §Ila-C for WHO-FC II. APAH = associated pulmonary arterial hypertension; BAS = balloon atrial septostomy; CCB = calcium channel blocker; ERA = endothelin receptor antagonist; IPAH = idiopathic pulmonary arterial hypertension; PDE5 I = phosphodiesterase type-5 inhibitor; WHO-FC = World Health Organization functional class.
Beraprost. Beraprost is the first chemically stable and orally active prostacyclin analogue. The RCT ALPHA-BET in Europe and a second in the USA with this compound have shown an improvement in exercise capacity that unfortunately persists only up to 3–6 months. There were no haemodynamic benefits. The most frequent adverse events were headache, flushing, jaw pain, and diarrhoea.

**Endothelin receptor antagonists**

Activation of the endothelin system has been demonstrated in both plasma and lung tissue of PAH patients. Although it is not clear if the increases in endothelin-1 plasma levels are a cause or a consequence of PH, these data support a prominent role for the endothelin system in the pathogenesis of PAH. This has resulted in regulatory authorities approval for the use of bosentan in PAH patients with congenital systemic-to-pulmonary shunts and Eisenmenger’s syndrome. Bosentan treatment is started at the dose of 62.5 mg twice daily and uptitrated to 125 mg twice daily after 4 weeks. In paediatric patients doses are reduced according to the body weight. Long-term observational studies have demonstrated the durability of the effect of bosentan in adult IPAH patients over time. Increases in hepatic aminotransferases occurred in ~10% of the subjects but were found to be dose dependent and reversible after dose reduction or discontinuation. For these reasons, liver function test should be performed monthly in patients receiving bosentan. Reductions on haemoglobin levels and impaired spermatogenesis have also been observed.

Sitaxentan. Sitaxentan, a selective orally active endothelin-A receptor antagonist, has been assessed in two RCTs (STRIDE 1 and 2) in WHO-FC II and III PAH patients. The current approved dose is 5 mg once daily which can be increased to 10 mg once daily when the drug is tolerated at the initial dose.

The incidence of abnormal liver function tests ranges from 0.8 to 3%. In a small group of patients in which treatment with either bosentan or sitaxentan was discontinued due to liver function test abnormalities, ambrisentan at a dose of 5 mg was well tolerated. Nevertheless, patients treated with ambrisentan require monthly liver function test assessment. An increased incidence of peripheral oedema has been reported with ambrisentan use.

**Phosphodiesterase type-5 inhibitors**

Inhibition of the cGMP-degrading enzyme phosphodiesterase type-5 results in vasodilatation through the NO/cGMP pathway at sites expressing this enzyme. Since the pulmonary vasculature contains substantial amounts of phosphodiesterase type-5 the potential clinical benefit of phosphodiesterase type-5 inhibitors has been investigated in PAH. In addition, phosphodiesterase type-5 inhibitors exert antiproliferative effects. All three phosphodiesterase type-5 inhibitors approved for the treatment of erectile dysfunction, sildenafil, tadalafil, and vardenafil, cause significant pulmonary vasodilatation, with maximum effects observed after 60, 75–90, and 40–45 min, respectively.

Sildenafil. Sildenafil is an orally active, potent, and selective inhibitor of phosphodiesterase type-5. A number of uncontrolled studies have reported favourable effects of sildenafil in IPAH, PAH associated with CTD, CHD, and CTEPH. An RCT (SUPER-1) on 278 PAH patients treated with sildenafil 20, 40, or 80 mg t.i.d. has confirmed favourable results on exercise capacity, symptoms, and haemodynamics. A post hoc analysis of 84 PAH patients associated with CTD patients receiving sildenafil in the SUPER-1 trial revealed improved exercise capacity, haemodynamic parameters, and functional class at 12 weeks when compared with placebo. The approved dose is 20 mg t.i.d., but the durability of effect up to a year has been demonstrated only with the dose of 80 mg t.i.d. In clinical practice, up-titration beyond 20 mg t.i.d. (mainly 40–80 mg t.i.d.) is needed quite frequently. The PACES trial addressing the effects of adding sildenafil to epoprostenol is discussed in the ‘Combination therapy’ section. Most side effects of sildenafil were mild to moderate and mainly related to vasodilation (headache, flushing, epistaxis).

Tadalafil. Tadalafil is a once-daily dispensed, selective phosphodiesterase type-5 inhibitor, currently approved for the treatment of erectile dysfunction. An RCT (PHIRST) on 406 PAH patients (~50% on background bosentan therapy) treated with tadalafil 5, 10, 20, or 40 mg once daily has shown favourable results on co-administration requires dose reductions of warfarin to avoid increases of INR (Table 20).

Exercise capacity, symptoms, haemodynamics, and time to clinical worsening at the largest dose. The durability of the effect has also been shown. The side effect profile was similar to that of sildenafil.

**Experimental compounds and alternative medical strategies**

Despite the progress on the treatment of PAH, the functional limitation and the survival of these patients remain unsatisfactory. For these reasons, additional therapeutic strategies targeted to diverse pathobiological changes are being explored in order to improve symptoms and prognosis further. Phase II and III studies are currently being performed with the following compounds: NO-independent stimulators and activators of cGMP, inhaled vasoactive intestinal peptide, non-prostanoid prostacyclin receptor agonists, tissular dual ERA-, tyrosine kinase inhibitors (platelet-derived growth factor inhibitors), and seroton antagonists.

The following additional compounds are in an earlier stage of development: rho-kinase inhibitors, vascular endothelial growth factor receptor inhibitors, angiopoietin-1 inhibitors, and elastase inhibitors.

Gene therapy strategies have been tested in animal models. Stem cell therapy has proven to be effective in the monocrotaline rat model and is currently being tested in proof-of-concept and dose-finding studies in PAH patients.

**Combination therapy**

The term combination therapy describes the simultaneous use of more than one PAH-specific class of drugs, e.g. ERAs, phosphodiesterase type-5 inhibitors, prostanoids, and novel substances. Combination therapy has become the standard of care in many PAH centres, although long-term safety and efficacy have not yet been amply explored. Numerous case series have suggested that various drug combinations appear to be safe and effective. In one series, a step-wise use of combination therapy according to predefined treatment goals was associated with an improved outcome compared with a historical control group.

Results of a few RCTs evaluating combination therapy for PAH have been published. The relatively small BREATHE-2 study showed a trend to a better haemodynamic effect of the initial combination epoprostenol-bosentan as compared to epoprostenol alone. The STEP-1 study addressed the safety and efficacy of 12 weeks therapy with inhaled iloprost in addition to bosentan and found a marginal increase in the post-inhalation 6 min walk distance by +26 m (P = 0.051). When measured at pre-inhalation, the placebo-corrected improvement in 6 min walk distance was +19 m (P = 0.14). There was no improvement in pre-inhalation haemodynamics in the iloprost group after 12 weeks of treatment, but time to clinical worsening was significantly prolonged in the iloprost group (0 events vs. 5 events in the placebo group; P = 0.02). In contrast, another RCT, COMBI, which also studied the effects of inhaled iloprost added to bosentan, was stopped prematurely after a planned futility analysis did not show an effect on 6 min walking distance or time to clinical worsening.

Two other RCTs on combination therapy have been concluded: TRIUMPH and PACE. TRIUMPH studied the effects of inhaled treprostinil in patients already treated with bosentan or sildenafil. The primary endpoint, change in 6MWT at peak exposure, improved by 20 m compared with placebo (P < 0.0006). At trough exposure, i.e. after >4 h post-inhalation, the difference was 14 m in favour of the treprostinil group (P < 0.01). There were no significant differences in Borg dyspnoea index, functional class, and time to clinical worsening.

The PACES trial addressed the effects of adding sildenafil to epoprostenol in 267 PAH patients. The most pertinent findings of this study were significant improvements after 12 weeks in 6MWT and time to clinical worsening. Of note, seven deaths occurred in this trial, all in the placebo group.

Additional data from RCTs are available for the combination of ERAs and phosphodiesterase type-5 inhibitors. In the subgroup of patients enrolled in the EARLY study (bosentan in WHO-FC II PAH patients) who were already on treatment with sildenafil, the haemodynamic effect of the addition of bosentan was comparable with that achieved in patients without background sildenafil treatment. A pharmacokinetic interaction has been described between bosentan and sildenafil, which act as inducers or inhibitors of cytochrome P450 CYP3A4, respectively. The co-administration of both substances results in a decline of sildenafil plasma levels and an increase in bosentan plasma levels. So far there is no indication that these interactions are associated with reduced safety, but the issue of whether the clinical efficacy of sildenafil is significantly reduced is still under debate. No pharmacokinetic interactions have been reported between sildenafil and the two other available ERAs, sitaxentan and ambrisentan.

In the PHIRST study the combination of tadalafil and bosentan resulted in an improvement of exercise capacity of borderline statistical significance (subgroup analysis). For these two compounds a pharmacokinetic interaction has also been shown (Table 20).

There are many open questions regarding combination therapy, including the choice of combination agents, the optimal timing [initial combination (in naive patients) or sequential combination (according to the response to the first drug)], when to switch, and when to combine. When combination therapy is considered, patients should be treated within clinical trials or registries whenever possible. Combination therapy of established PAH drugs is recommended for patients not responding adequately to monotherapy, but combination therapy should be instituted by expert centres only. Whether the response to monotherapy is sufficient or not can only be decided on an individual basis. This is judged in an individual patient who, despite monotherapy and optimized background treatment, has an inadequate clinical response (Figure 2 and Table 22).

The safety and efficacy of tyrosine kinase inhibitors in PAH must be further evaluated and, at present, the use of these drugs should be restricted to RCTs.

**Drug interactions**

Significant drug interactions involving the disease-specific therapies for PAH are shown in Table 20. This table highlights known important interactions but does not include theoretical untested interactions, which may still be clinically important.

Bosentan is an inducer of cytochrome P450 isoenzymes CYP3A4 and CYP2C9. Plasma concentrations of drugs
metabolized by these isoenzymes will be reduced when co-administered with bosentan. Bosentan is also metabolised by these enzymes so that their inhibition may increase the plasma concentration of bosentan. In addition to interactions shown in Table 20, a combination of a potent CYP3A4 inhibitor (ketoconazole or ritonavir) and/or a CYP2C9 inhibitor (e.g. amiodarone of fluconazole) with bosentan may cause a potentially contraindicated significant increase in plasma bosentan levels and it is contraindicated. Interactions may theoretically occur with iraconazole, tacrolimus, sirolimus, carbamazepine, phenytoin, phenobarbital, dapsone, and St John’s Wort.

Sildenafil is an inhibitor of cytochrome P450 isoenzyme CYP2C9 and a weak inhibitor of CYP3A4/5, CYP2C19, and CYP3A4. It is metabolized by CYP2C9 and CYP3A4/5. Sildenafil may also be a substrate for organic anion transporter proteins, and plasma sildenafil levels may be elevated by drugs that interact with organic anion transporter proteins such as cyclosporine, some statins, and drugs for tuberculosis. When administered with oral contraceptive agents, sildenafil increases oestrogen exposure, which may result in a theoretically greater risk of thromboembolism.

Sildenafil is metabolized by cytochrome P450 isoenzymes CYP2C9 (major route) and CYP3A4 (minor route). There is an increase in sildenafil bioavailability and reduced clearance with CYP2C9 substrates, and CYP3A4 substrates plus beta-adrenoceptor blockers. CYP3A4 inducers such as carbamazepine, phenytoin, phenobarbital, rifampicin and St John’s Wort may significantly lower sildenafil levels. Sildenafil levels are modestly increased by fresh grapefruit juice, a weak inhibitor of CYP3A4.

Finally, care is needed when PAH-specific medications are co-administered with antihypertensive drugs such as beta-adrenoceptor blockers, angiotensin-converting enzyme inhibitors, etc., to avoid excessive systemic hypotension.

7.3.4 Treatment of arrhythmias

Arrhythmias are an increasing clinical problem in PAH patients. In contrast to patients with left heart disease, malignant ventricular arrhythmias such as ventricular tachycardia, ventricular flutter, and ventricular fibrillation are rare in PAH patients. In a series of 132 witnessed cardiac arrests in patients with PAH, ventricular fibrillation was observed in only 8% of the cases. Another series of 231 patients with PAH or CTEPH followed over a 6-year period did not report any case of malignant ventricular arrhythmia. In that series, supraventricular tachyarrhythmias occurred with an annual incidence of 2.8%. Atrial flutter and atrial fibrillation were equally common and both arrhythmias invariably led to clinical deterioration with signs of right heart failure. Treatment of atrial flutter proved to be more successful than treatment of atrial fibrillation. Restoration of a stable sinus rhythm was associated with a favourable long-term survival while persistent atrial fibrillation was associated with a 2-year mortality of >80%. Although prospective and controlled data are lacking, these findings suggest that maintenance of a stable sinus rhythm should be considered an important treatment goal in patients with PAH. In order to achieve a stable sinus rhythm, prophylaxis with antiarrhythmic drugs without negative inotropic effects such as amiodarone (see interactions in Table 20) should also be considered even if specific data regarding its efficacy are lacking.

7.3.5 Balloon atrial septostomy

Patients with Eisenmenger’s syndrome and patients with IPAH with a patent foramen ovale have a survival advantage over those without a patent foramen ovale, supporting the concept of atrial septostomy as a treatment for IPAH. The creation of an inter-atrial right-to-left shunt can decompress the right heart chambers, and increase LV preload and CO. In addition, this improves systemic O2 transport despite arterial O2 desaturation and decreases sympathetic hyperactivity. The recommended technique is graded balloon dilatation atrial septostomy, which produces equivalent improvements in haemodynamics and symptoms but reduced risk compared with the original blade technique. Other techniques are considered to be experimental.

A careful pre-procedure risk assessment ensures reduced mortality. Balloon atrial septostomy (BAS) should be avoided in end-stage patients presenting with a baseline mean RAP of >20 mm Hg and O2 saturation at rest of <80% on room air. Patients should be on optimal medical therapy, which may include pre-conditioning with i.v. inotropic drugs, prior to considering BAS. Evidence suggests a benefit in patients who are in WHO-FC IV with right heart failure refractory to medical therapy or with severe syncopal symptoms. It may also be considered in patients awaiting transplantation or when medical therapy is not available. Severe IPAH has been the main indication for BAS in adults, although other indications include PAH associated with surgically corrected CHD, CTD, distal CTEPH, PVOD, and pulmonary capillary haemangiomatosis.

Evidence shows improvements in CI, decreases in right atrial pressure with improvement in 6MWT.

The impact of BAS on long-term survival has not been established in RCTs. BAS should be regarded as a palliative or bridging procedure to be performed only by centres with experience in the method.

7.3.6 Transplantation

The advent of disease-specific therapy for severe PAH has reduced patient referral for lung transplant programmes. The long-term outcomes of medically treated patients remains uncertain and transplantation should remain an important option for those who fail on such therapy. Studies indicate that up to 25% of patients with IPAH may fail to improve on disease-specific therapy and the prognosis of patients who remain in WHO-FC III or IV is poor. International guidelines to aid referral and listing have been published by the International Society for Heart and Lung Transplantation.

The prognosis of PAH varies according to the aetiology, and PAH associated with CTD has a worse prognosis than IPAH even when treated with prostanoids, while patients with PAH associated with CHD have a better survival. The worst prognosis is seen in patients with PVOD and pulmonary capillary haemangiomatosis because of the lack of effective medical treatments, and those patients should be listed for transplantation at diagnosis.

In any case, patients with features identifying a worse prognosis profile (Table 15) despite maximal medical therapy should be referred for transplant listing.

Both heart-lung and double-lung transplantation have been performed for PAH, although the threshold of unrecoverable RV
systolic dysfunction and/or LV diastolic dysfunction is unknown. As a consequence, each centre has developed its own strategy for the choice of the type of transplantation in the individual patient. However, due to the shortage of donor organs, most patients are considered for double-lung transplantation. While RV afterload is immediately reduced after double-lung transplantation, RV systolic and LV diastolic functions do not improve immediately and haemodynamic instability is a common problem in the early post-operative period. Both single and bilateral procedures have been performed, apparently with similar survival. However, any complication occurring in the allograft following single lung transplantation is associated with severe hypoxaemia. Currently the vast majority of patients worldwide receive bilateral lungs, as evidenced by the International Society for Heart and Lung Transplantation Registry figures.174

Although patients with Eisenmenger’s syndrome due to simple shunts have been treated by isolated lung transplantation and repair of the cardiac defect,174 patients with ventricular septal defects may have a better outcome with heart–lung transplantation.175

The overall 5-year survival following transplantation for PAH is 45–50%, with evidence of continued good quality of life.174

7.3.7 Treatment algorithm

A treatment algorithm for PAH patients176 is shown in Figure 2. The grades of recommendation and levels of evidence for the PAH treatments177 are shown also in Table 21. The definition of clinical response to treatments is reported in Table 22. Country-specific regulatory approval and labelling for PAH medical treatments are shown in Table 23. Potential drug interactions are shown in Table 20.

- Drug classes are listed in alphabetical order (ERAs, phosphodiesterase type-5 inhibitors, prostanoids) and single compounds are listed in alphabetical order within each class in Figure 2 and Tables 21 and 23.
- The treatment algorithm does not apply to patients in other clinical groups, and in particular not to patients with PH associated with group 2—left heart disease or with group 3—lung diseases. In addition, the different treatments have been evaluated by RCTs mainly in IPAH, heritable PAH, PAH due to anorexigen drugs, and in PAH associated with CTD or with CHD (surgically corrected or not). The grades of recommendation and levels of evidence for the other PAH subgroups are lower (see the section on specific PAH subsets).
- The suggested initial approach after the diagnosis of PAH, is the adoption of the general measures, the initiation of the supportive therapy, and referral to an expert centre.
- Acute vasoreactivity testing should be performed in all patients with group 1—PAH, although patients with IPAH, heritable PAH, and PAH associated with anorexigen use are the most likely to exhibit an acute positive response and to benefit from high-dose CCB therapy. Vasoreactive patients, as defined above, should be treated with optimally tolerated doses of CCBs (see section 7.3.3); adequate response should be confirmed after 3–4 months of treatment.
- Non-responders to acute vasoreactivity testing who are in WHO-FC II should be treated with an ERA or a phosphodiesterase type-5 inhibitor.

*aOnly in responders to acute vasoreactivity tests, I for idiopathic PAH, heritable PAH, and PAH due to anorexigens; IIA for APAH conditions.
*bUnder regulatory review in the European Union.
In the case of inadequate clinical response (Table 22), initial combination therapy should also be considered. Although ambrisentan, bosentan, and sildenafil are approved in New Zealand, approval of the subcutaneous form of treprostinil has been slow. Continuous i.v. epoprostenol is recommended as first-line therapy for WHO-FC IV PAH patients because of the survival benefit in this subset. In the USA, only a small number of these patients were included in the RCTs of these agents. Accordingly, most experts consider these treatments as a second line in severely ill patients. As head-to-head comparisons among different compounds are not available, no evidence-based first-line treatment can be proposed. In this case the choice of the drug is dependent on a variety of factors including the approval status, the route of administration, the side effect profile, patients’ preferences, and physicians’ experience. Some experts still use first-line i.v. epoprostenol in WHO-FC III patients because of its survival benefits. Non-responders to acute vasoreactivity testing, or responders who remain in (or progress to) WHO-FC III should be considered candidates for treatment with either an ERA or a phosphodiesterase type-5 inhibitor, or a prostanooid.

As head-to-head comparisons among different compounds are not available, no evidence-based first-line treatment can be proposed. In this case the choice of the drug is dependent on a variety of factors including the approval status, the route of administration, the side effect profile, patients’ preferences, and physicians’ experience. Some experts still use first-line i.v. epoprostenol in WHO-FC III patients because of its survival benefits. Continuous i.v. epoprostenol is recommended as first-line therapy for WHO-FC IV PAH patients because of the survival benefit in this subset. S.c. and i.v. treprostinil have been also approved for the treatment of WHO-FC IV patients in the USA. Although no RCTs have been performed with the i.v. delivery of iloprost, this prostacyclin analogue has been approved in New Zealand. Although ambrisentan, bosentan, and sildenafil are approved in WHO-FC IV patients in the USA, only a small number of these patients were included in the RCTs of these agents. Accordingly, most experts consider these treatments as a second line in severely ill patients. In WHO-FC IV patients, initial combination therapy should also be considered. In the case of inadequate clinical response (Table 22, Figure 2), sequential combination therapy should be considered. Combination therapy can include either an ERA plus a phosphodiesterase type-5 inhibitor, or a prostanooid plus an ERA, or a prostanooid plus a phosphodiesterase type-5 inhibitor. Appropriate protocols for timing and dosing to limit possible side effects of the combination have still to be defined. In expert centres also triple combination therapy is considered. BAS and/or lung transplantation are indicated for PAH with inadequate clinical response (Table 22) despite optimal medical therapy or where medical treatments are unavailable. These procedures should be performed only in experienced centres.

*Specifically approved also for PAH associated with congenital systemic-to-pulmonary shunts and Eisenmenger’s physiology.

As head-to-head comparisons among different compounds are not available, no evidence-based first-line treatment can be proposed. In this case the choice of the drug is dependent on a variety of factors including the approval status, the route of administration, the side effect profile, patients’ preferences, and physicians’ experience. Some experts still use first-line i.v. epoprostenol in WHO-FC III patients because of its survival benefits.

7.3.8 End of life care and ethical issues

The clinical course of PH is one of progressive deterioration interspersed with episodes of acute decompensation. It is difficult to predict when patients will die because death may come either suddenly or slowly because of progressive heart failure. It has been shown that physicians caring for patients tend to be overoptimistic in their prognostication and frequently misunderstand their patients’ wishes. Open and sensitive communication with patients allows advanced planning and discussion about their fears, concerns, and wishes, which is essential to good care. Opportunities to...
discuss prognosis should be created at the time of initial diagnosis. Recognition that cardiopulmonary resuscitation in severe PH has poor outcomes may enable a ‘do not resuscitate’ order. This may increase the chance of patients being in their preferred place of care at the end of life.

Patients approaching the end of life require frequent assessment of their full needs by a multidisciplinary team. Attention should be given to controlling the distressing symptoms and prescribing appropriate drugs while withdrawing unnecessary medication. Well-informed psychological, social, and spiritual support is also vital. Specialist palliative care should be consulted about patients whose needs are beyond the expertise of the PH team.

7.4 Specific pulmonary arterial hypertension subsets

Some conditions included in the group 1—PAH, although presenting similarities with IPAH, bear sufficient differences to require specific comments. These conditions comprise paediatric PAH and APAH forms (Table 4) such as CHD, CTD, portal hypertension, and HIV infection. Recognition of these differences is critical because they may influence not only the diagnostic approach but also the global management of PAH.

7.4.1 Paediatric pulmonary arterial hypertension

Paediatric PH is similar to adult disease even if the lungs are still developing in a growing child. The worse prognosis in children with a median survival estimated at 10 months compared with 2.8 years in the adult has not been confirmed. The exact incidence and prevalence of PH in children is not known. All forms of PH included in the clinical classification (Table 4) have been described in children, but the majority of patients present with PH associated with CHD or idiopathic/heritable forms. In contrast, the prevalence of PH associated with CTD, portal hypertension, HIV infection, and drugs and toxins is lower. Children with chronic lung disease or prematurity are a growing population. Persistent PH of the neonate is also classified under PAH. Its natural history, treatment, and outcome are sufficient to justify its exclusion from this discussion.

No clear differences have been identified among the mechanisms involved in the development of PAH in children and adults.

Diagnosis

Based on old studies it was thought that 40% of children with IPAH were vasoreactive, but it seems that new figures are closer to those of the adult patient population, with a range of 10–15% of acute responders or even less.

Children often present sicker than adults. Dyspnoea, fatigue, and failure to thrive are common symptoms. Syncope is more frequent in the child, but overt RV failure is a late event and the child may die suddenly before the appearance of RV failure. A similar diagnostic work-up to that in the adult is suggested. Even if some associations are rare they should be excluded before a definite diagnosis. A thorough family and personal history with pregnancy, delivery, and postnatal details is essential. 6MWT and cardiopulmonary exercise testing can be performed but require expertise and should be adapted to age. Diagnosis requires RHC and vasoreactivity testing which are performed as in adults. In children these procedures may require general anaesthesia, which increases the risks.

Therapy

The response to therapy is difficult to predict, with some patients having a dramatic response and some requiring rapid escalation of therapy. The therapeutic algorithm used for children is similar to the one used in adults even if specific RCTs are lacking. Several expert centres have suggested specific, but indeed very similar, treatment algorithms. Only a few studies have been performed to confirm the exact dose of new therapies to be applied in children.

Therapy should include close follow-up. Rapid treatment of any upper or lower airway infection is essential because of the danger of a rapid deterioration. The use of anticoagulation is controversial as no studies are available in children. The risk–benefit profile is a problem in small children. The use of aspirin instead of coumadin is also controversial. The consensus is to anticoagulate patients with overt right heart failure.

CCBs are used in responders, but close follow-up is mandatory as patients may fail long-term therapy.

Data are available with bosentan, the pharmacokinetics of which have been assessed in one study. Several uncontrolled studies in children have shown positive results similar to adults, with survival rates of 80–90% at 1 year. A new paediatric formulation has been recently approved by the European Medicines Agency. Data about selective endothelin-A receptor antagonists are not available so far.

Sildenafil has shown some efficacy, and an RCT is underway to define dose and efficacy.

Indications for epoprostenol are similar to those in adults. The usual starting dose is 2 ng/kg/min with a rapid increase. Optimal doses vary considerably between patients and thus individual titration is required. Administration of i.v. iloprost and trepostinil has been reported as in adults. Oral beraprost is only used in some countries, but lack of proof of efficacy is a problem. S.c. treprostinil may be an option, but local pain is a serious problem in children. Inhaled iloprost is also difficult, but a recent report has shown some efficacy.

An increasing number of paediatric patients are on combination therapy even though evidence is still lacking. Atrial septostomy as well as a Pott’s shunt are possible in children, with good results. As in adults, cure of PAH is only obtained with lung transplantation, but lack of suitable donors is a major problem.

Recommendations for pediatric PAH are summarized in the Table 24.
7.4.2 Pulmonary arterial hypertension associated with congenital cardiac shunts

PAH associated with CHD is included in group 1 of the PH clinical classification (Table 4). A specific clinical classification (Table 6) and an anatomical–pathophysiological classification (Table 7) are useful to better define each individual patient with PAH associated with CHD.1,16

Epidemiological data remain scarce as no studies were designed to assess the prevalence of PAH in adult CHD, although 5–10% was suggested in a recent study.189 The persistent exposure of the pulmonary vasculature to increased blood flow due to systemic-to-pulmonary shunts as well as increased pressure may result in a typical pulmonary obstructive arteriopathy (identical to other PAH forms) that leads to the increase of PVR. If PVR approaches or exceeds systemic vascular resistance, the shunt is reversed (Eisenmenger’s syndrome).190

Diagnosis

The signs and symptoms of Eisenmenger’s syndrome result from PH, low arterial O2 saturation, and secondary erythrocytosis. They include dyspnoea, fatigue, and syncope. In patients with PAH associated with CHD without reversal of the shunt, the degree of cyanosis and erythrocytosis may be mild to moderate. Eisenmenger’s syndrome patients also suffer from haemoptysis, cerebrovascular accidents, brain abscesses, coagulation abnormalities, and sudden death. Subjects with Eisenmenger’s syndrome have reduced life expectancy, although many survive into their third or fourth decade, with some even surviving into their seventh decade.191 In patients listed for lung or heart–lung transplantation when no medical treatment was available, Eisenmenger’s syndrome had better survival compared with IPAH, with a 3-year survival rate of 77% compared with 35% for untreated IPAH.192 Of all patients with CHD, those with Eisenmenger’s syndrome are the most severely compromised in terms of exercise intolerance.193

Improved survival may result possibly from preservation of RV function as the RV does not undergo remodelling at birth and remains hypertrophied.194 The RV is also relieved by the right-to-left shunt, sustaining systemic CO, at the expense of hypoxaemia and cyanosis.

Patients with CHD (in particular those without shunts) may also develop PH due to left heart disease (group 2, Table 4) or to concomitant lung diseases (group 3, Table 4). In these cases a comprehensive diagnostic work-up, as reported in section 7.1.12, is recommended.

Therapy

The treatment strategy for patients with PAH associated with CHD and in particular for subjects with Eisenmenger’s syndrome is mainly based on the clinical experience of experts rather than formally evidence based.190 A specific treatment algorithm similar to that in Figure 2 has been recently proposed.16

Eisenmenger’s syndrome patients should be managed in specialized centres. Patient education, behavioural modifications, and awareness of potential medical risk factors are important aspects of management.

Patients with Eisenmenger’s syndrome may present with clinical deterioration in different circumstances, including non-cardiac surgery with general anaesthesia, dehydration, lung infections, and high altitude. It is recommended to avoid strenuous exercise but mild activities seem to be beneficial. Pregnancy is associated with high risk to both mother and fetus. Pregnancy should be discouraged, and contraception is indicated.

Long-term home O2 therapy may improve symptoms, but has not been shown to modify survival, at least when given only at night.111 The use of supplemental O2 therapy is recommended in cases in which it produces a consistent increase in arterial oxygen saturation and reduces symptoms.

The use of oral anticoagulant treatment in Eisenmenger’s syndrome is controversial: a high incidence of PA thrombosis and stroke is reported but there is also an increased risk of haemorrhage and haemoptysis.195 No data exist on this issue and definite recommendations cannot therefore be made. Oral anticoagulant treatment may be considered in patients with PA thrombosis, signs of heart failure, and absent or only mild haemoptysis.

Secondary erythrocytosis is beneficial for adequate O2 transport and delivery, and routine phlebotomy should be avoided. If symptoms of hyperviscosity are present, phlebotomy with isovolumic replacement should be performed, usually when the haematocrit is >65%. Iron deficiency should be corrected. No clear data support the use of CCBs in patients with Eisenmenger’s syndrome, and the empirical use of CCBs is dangerous and should be avoided.

One RCT is available with specific drug therapy: bosentan has been shown to improve 6MWT and decrease PVR after 16 weeks of treatment in WHO-FC III patients.142 The long-term follow-up (40 weeks) showed sustained improvement.194 Bosentan is currently approved in Europe for WHO-FC III Eisenmenger’s syndrome patients. No studies are available with the use of other ERAs in this setting.

Anecdotal experiences with the phosphodiesterase type-5 inhibitors sildenafil197 and tadalafil198 show favourable functional and haemodynamic results in patients with PAH associated with CHD and Eisenmenger’s syndrome.

The use of i.v. epoprostenol has been reported in Eisenmenger’s syndrome patients, with favourable effects on haemodynamics and exercise capacity, although central lines expose the patients to the risk of paradoxical embolism and sepsis.120 No data are available with the use of other prostanooids.

There are no published data on combination therapy, but the rationale is the same as in IPAH. Since the introduction of targeted therapies in Eisenmenger’s syndrome, there is growing interest in pre-Eisenmenger’s syndrome patients considered inoperable on the basis of haemodynamic changes (PVR too high) in order to remodel the pulmonary vascular bed and perform interventional or surgical correction. No recommendation can be given in this setting as only anecdotal cases have been reported.

Heart–lung or lung transplantation with heart surgery is an option in special cases not responsive to medical treatment, but is limited by organ availability. Short- and long-term survival rates following heart–lung transplantation are similar to other forms of PAH. The prolonged estimated survival of patients with Eisenmenger’s syndrome makes the decision if and when patients should be listed difficult.16

Recommendations for pulmonary arterial hypertension associated with congenital cardiac shunts are summarized in the Table 25.
7.4.3 Pulmonary arterial hypertension associated with connective tissue disease

PAH is a well-known complication of CTDs such as systemic sclerosis,114 systemic lupus erythematosus, mixed CTD, and, to a lesser extent, rheumatoid arthritis, dermatomyositis, and Sjögren’s syndrome. PAH associated with CTD is the second most prevalent type of PAH after IPAH in registries.3,4

Systemic sclerosis, particularly in its limited variant (CREST syndrome), represents the main CTD associated with PAH. The prevalence of haemodynamically proven PAH in large cohorts of patients with systemic sclerosis is between 7 and 12%.2,114 In these patients, PAH may occur in association with interstitial fibrosis or as a result of an isolated pulmonary arteriopathy. In addition, pulmonary venous hypertension from left heart disease may be present. It is imperative to determine which mechanism is operative since this dictates treatment.

Histopathological changes in PAH associated with CTD are generally indistinguishable from those of classical IPAH, although there is more frequent involvement of the pulmonary veins.199 The pathophysiological mechanisms leading to PAH in patients with CTD remain unknown. The presence of antinuclear antibody, rheumatoid factor, immunoglobulin G, and complement fraction deposits in the pulmonary vessels wall suggest a role for an immunological mechanism.

Diagnosis

Compared with IPAH, patients with CTD and PAH are mainly women (women/men ratio 4:1), are older (mean age at diagnosis, 66 years), may present concomitant disorders (pulmonary fibrosis, left heart disease), and have shorter survival.114 The unadjusted risk of death for systemic sclerosis-associated PAH compared with IPAH is 2.9200 and the predictors of outcome are the same as for IPAH (RAP, PAP, and CI). Symptoms and clinical presentation are very similar to those of IPAH and occasional patients thought to have IPAH can be identified as having an associated CTD by immunological screening tests. High-resolution CT is helpful for evaluating the presence of associated interstitial lung disease. An isolated reduction of diffusion capacity of carbon monoxide is a frequent abnormality in systemic sclerosis associated with PAH.

Echocardiographic screening for the detection of PH has been recommended annually in asymptomatic patients with the scleroderma spectrum of diseases but only in the presence of symptoms in other CTDs. The cost-effectiveness of this strategy has not been clarified as compared with symptom-based screening (see also section 7.1.5). As in other forms of PAH, RHC is recommended in all cases of suspected PAH associated with CTD to confirm the diagnosis, determine severity, and rule out left-sided heart disease. RHC is mandatory if targeted treatments are considered. The proportion of responders in the acute vasodilator test is lower than in IPAH.66

Therapy

Treatment of patients with PAH associated with CTD appears more complex than that of patients with IPAH. Immunosuppressive therapy combining glucocorticosteroids and cyclophosphamide may result in clinical improvement in patients with PAH associated with systemic lupus erythematosus or mixed CTD.201 Long-term favourable response to CCB treatment in vasoreactive patients is seen less often than in IPAH. The risk-to-benefit ratio of oral anticoagulation is not well understood.

Treatment of patients with CTD and PAH should follow the same treatment algorithm as in IPAH (Figure 2). This recommendation is based on the fact that patients with CTD have been included in most of the major RCTs for regulatory approval of PAH therapy, including those with combination therapy.

Subgroup analyses of patients with scleroderma enrolled in the RCTs performed with bosentan,139 sitaxsentan,202 sildenafil,155 and mifepristone have shown favourable effects. In some of these trials the magnitude of the response in the PAH subgroup associated with CTD was lower than in IPAH.

Continuous i.v. epoprostenol therapy has been shown to improve exercise capacity, symptoms, and haemodynamics in a 3-month RCT of patients with the scleroderma spectrum of the diseases.199 Retrospective analysis shows, however, that the effect of i.v. epoprostenol on survival of IPAH patients seems to be better than that of of scleroderma patients. The presence of a CTD is not a contra-indication for lung transplantation per se if medical treatments fail.

Recommendations for pulmonary arterial hypertension associated with CTD are summarized in the Table 26.

7.4.4 Pulmonary arterial hypertension associated with portal hypertension

PAH is a well-recognized complication of chronic liver diseases.204,205 Portal hypertension rather than the hepatic disorder itself seems to be the main determining risk factor for developing PAH.204 The condition is not uncommon since PAH associated with portal hypertension (also named as portopulmonary hypertension)

represents ∼10% of the PAH population.³ It is believed that 1–2% of patients with liver disease and portal hypertension develop PAH, but the prevalence of PAH may reach 5% among patients with advanced liver disease evaluated for liver transplantation.²⁰⁶ The pathogenesis is unclear and may be related to toxic substances derived from the gastrointestinal tract, which are not eliminated by the liver due to portosystemic shunts, thus causing damage to the lung endothelium. Another possibility is that the high CO state is inducing PAH.

Diagnosis

The clinical picture of patients with portopulmonary hypertension may be indistinguishable from that of those with IPAH or may include a combination of symptoms and signs of the underlying liver disease.²⁰⁴ Echocardiographic screening for the detection of PH in patients with liver diseases is appropriate in symptomatic patients and/or in candidates for liver transplantation. An RHC should be performed in all cases with increased systolic PAP in order to clarify the underlying haemodynamic changes and define prognostic and therapeutic implications. Patients with portopulmonary hypertension have a significantly higher CO and significantly lower systemic vascular resistance and PVR, compared with patients with IPAH. In a retrospective study,²⁰⁴ patients with portopulmonary hypertension had a better rate of survival than patients with IPAH, although this is debated.

Therapy

Portopulmonary hypertension is part of the PAH spectrum of disease and in general these patients should be treated similarly to those with other forms of PAH, while taking into consideration the presence of liver disease and its consequences for their management. The treatment algorithm (Figure 2) can also be applied in this setting with adaptations.

Anticoagulant therapy should be avoided in patients at increased risk of bleeding. β-Adrenoceptor blockers, often used in patients with portal hypertension to reduce the risk of variceal bleeding, worsen haemodynamics and exercise capacity in portopulmonary PAH patients.²⁰⁷

Patients with portopulmonary hypertension have been excluded from almost all RCTs in PAH. Case series suggest that epoprostenol, bosentan, and sildenafil may exert beneficial haemodynamic and clinical effects in selected patients.²⁰⁸–²¹⁰ In a retrospective study treatment with bosentan appeared to be better than inhaled iloprost.²¹¹ Careful monitoring should be performed if ERA treatment is initiated because of the hepatotoxicity of these compounds.

PAH can substantially increase the risk associated with liver transplantation and usually PAH is a contraindication if mean PAP is ≥ 35 mmHg and/or PVR is ≥ 250 dynes.s.cm⁻².²⁰⁶,²¹² It has been suggested that PAH-specific drug therapy should be used to improve haemodynamics prior to liver transplantation, but the effects on the outcome of liver transplantation have not been evaluated sufficiently.

Selected patients with end-stage liver disease and severe PH may be considered for combined liver–lung or liver–heart–lung transplantation. The largest series of combined liver–lung transplantation so far has reported a 3-year survival of 62%. This treatment option is offered by only a few centres worldwide.²¹³

Recommendations for pulmonary arterial hypertension associated with portal hypertension are summarized in the Table 27.

7.4.5 Pulmonary arterial hypertension associated with human immunodeficiency virus infection

The use of highly active antiretroviral therapy and aggressive management of opportunistic infections has contributed to increased life expectancy in HIV-infected patients. Consequently, the spectrum of complications has shifted towards other long-term conditions, including cardiovascular diseases such as dilated cardiomyopathy, pericardial disorders, non-infectious thrombotic
endothelin receptors antagonist ambrisentan, allowed inclusion and i.v. drug abusers. More than 80% are well controlled on abuse. Patients with HIV-related PAH are more likely to be male similar to before the highly active antiretroviral therapy era. The minimal prevalence of HIV-related PAH was 0.46%, very conducted in France contradicts this hypothesis because the calculated incidence of HIV-related PAH was 0.1%, very similar to before the highly active antiretroviral therapy era.

The pathogenesis of HIV-related PAH remains unclear. The absence of viral particles in the complex plexiform lesions found from these patients suggests that an indirect action of viral infection on inflammation and growth factors may act as a trigger on a predisposed patient.

Diagnosis
HIV-related PAH shares a similar clinical presentation with IPAH. At the time of diagnosis, 71–81% of patients are in an advanced WHO-FC. Patients may present with other risk factors for PAH such as liver disease (chronic hepatitis B or C), exposure to drugs and toxins, or pulmonary embolism due to i.v. drug abuse. Patients with HIV-related PAH are more likely to be male and i.v. drug abusers. More than 80% are well controlled on highly active antiretroviral therapy, and CD4 count does not appear to be a risk factor for PAH.

Asymptomatic HIV-infected patients should not be screened for PAH. Echocardiography must be performed in patients with unexplained dyspnoea to detect HIV-related cardiovascular complications such as myocarditis, cardiomyopathy, or PAH. An RHC confirmation is mandatory to establish the diagnosis of HIV-related PAH and the absence of left heart disease. PAH is an independent risk factor for death in HIV-infected patients, with a 3-year survival rate as low as 21% in the most advanced cases (WHO-FC III/IV), compared with 84% in mildly symptomatic patients. In a single-centre study, a better outcome was associated with CD4 count >212 cells/µl, highly active antiretroviral therapy, and epoprostenol therapy.

Therapy
Treatment of HIV-related PAH is less well established in comparison with other forms of PAH. Only three RCTs, one with the orally active prostanoid beraprost and two with the selective endothelin receptors antagonist ambrisentan, allowed inclusion of patients with HIV-related PAH who represented <5% of the total population.

Anticoagulation is not routinely recommended because of an increased risk of bleeding, anticipated compliance issues, and drug interactions. Patients with HIV-related PAH appear to be non-responders to vasoreactivity tests and thus should not receive CCBs.

Several uncontrolled studies suggest that i.v. epoprostenol, s.c. treprostinil, and inhaled iloprost may improve exercise tolerance, haemodynamics and symptoms in HIV-related PAH.

Two open-label studies reported the effects of bosentan in patients with HIV-related PAH showing an improvement in all efficacy measures, including 6MWT, WHO-FC, Doppler-derived haemodynamic variables, and invasive haemodynamics. Hepatic tolerability was similar to previously reported observations in other forms of PAH. The interpretation of these studies is limited by the small sample size and the open-label nature.

In the case of use of sildenafil, the dose should be adjusted if ritonavir and saquinovir are co-administered due to drug–drug interactions (Table 20).

HIV infection is generally considered an exclusion criterion for lung transplantation even if in some centres a specific programme has been implemented.

Recommendations for pulmonary arterial hypertension associated with HIV infection are summarized in the Table 28.

8. Pulmonary veno-occlusive disease and pulmonary capillary haemangiomatosis (group 1')
Both PVOD and pulmonary capillary haemangiomatosis are uncommon conditions, but are increasingly recognized as causes of PAH. They have been classified in a specific subgroup of the clinical classification (Table 4, group 1') for the pathological, clinical, and therapeutic differences with the other forms of PAH included in group 1. Fewer than 200 cases of PVOD and pulmonary capillary haemangiomatosis have been reported in the literature. PVOD and pulmonary capillary haemangiomatosis are similar in some respects particularly in relation to the changes in the pulmonary parenchyma which have been described above.

Familial occurrence of PVOD has been reported, and a bone morphogenetic protein receptor-2 mutation has been found in a patient with this disease. These findings suggest that PAH and PVOD may represent different phenotypic manifestations of a spectrum of a single disease. In contrast to IPAH, there is a male predominance in PVOD and the prognosis appears to be worse.

8.1 Pulmonary veno-occlusive disease
8.1.1 Diagnosis
The diagnosis of PVOD can be established with a high probability by the combination of clinical suspicion, physical examination,
bronchoscopies, and radiological findings. This non-invasive approach may avoid lung biopsy (the gold standard to confirm a diagnosis of PVOD) in most of the cases. Most patients complain of dyspnoea on exertion and fatigue, a clinical presentation that is indistinguishable from IPAH. Physical examination may reveal digital clubbing and bi-basal crackles on auscultation, these being unusual in other forms of PAH. Case series suggest that patients with PVOD are more severely hypoxaemic and have a much lower diffusion capacity of carbon monoxide than in other forms of PAH. This can be explained by the presence of chronic interstitial pulmonary oedema typical of PVOD and/or a low CO state and/or the presence of a patent foramen ovale.

Chest radiograph may reveal Kerley B lines and peripheral interstitial infiltrate in addition to other typical signs of PH.

High-resolution CT scanning is the investigation of choice. Typical findings suggestive of PVOD are the presence of subpleural thickened septal lines, centrilobular ground-glass opacities (contrasting with a panlobular distribution found in IPAH), and mediastinal lymphadenopathy. The association of these three findings was found to be 100% specific for PVOD in cases of PAH, with a 66% sensitivity. In addition, their presence appears to correlate closely with the risk of pulmonary oedema with epoprostenol therapy.

Because PVOD may be associated with occult alveolar haemorrhage, bronchoscopy with bronchoalveolar lavage may be a useful tool in the diagnostic strategy. In a retrospective study, the results of bronchoalveolar lavage performed in 19 patients with suspicion of IPAH were analysed. Compared with IPAH, the eight cases of PVOD had a much lower diffusion capacity of carbon monoxide than in other forms of PAH. This can be explained by the presence of chronic interstitial pulmonary oedema typical of PVOD and/or a low CO state and/or the presence of a patent foramen ovale.

8.2.2 Therapy

There is no established medical therapy for PVOD. Most importantly, vasodilators and especially prostanooids must be used with great caution because of the high risk of pulmonary oedema. However, there are reports of sustained clinical improvement in individual patients treated with these medications. There are no data regarding the use of newer medical therapies such as ERAs or phosphodiesterase type-5 inhibitors in the treatment of PVOD and pulmonary capillary haemangiomatosis. Therefore, therapy for PVOD should be undertaken only at centres with extensive experience in the management of PH, and patients should be fully informed about the risks. Atrial septostomy may be considered but is usually limited by hypoxaemia. The only curative therapy for PVOD and pulmonary capillary haemangiomatosis is lung transplantation, and similarly to IPAH there are no reports of recurrence of disease following transplantation. Patients with PVOD should be referred to a transplant centre for evaluation as soon as the diagnosis is established.

Recommendations for PVOD are summarized in the Table 29.

8.2 Pulmonary capillary haemangiomatosis

This very rare condition may be difficult to differentiate from PVOD, and the diagnostic and therapeutic aspects are very similar. Often, only pathological examination is able to distinguish the two conditions.

9. Pulmonary hypertension due to left heart disease (group 2)

Most of the advances in the treatment of PH have been made in PAH. At the same time, virtually no progress has been made for the much more common forms of PH as encountered in patients with left heart diseases, lung diseases, or CTEPH. Despite the lack of data, drugs with proven efficacy in PAH are increasingly being used for other forms of PH. This may be clinically justified in some carefully selected patients but may turn out to be useless or even harmful in many others. This development is of concern, and the use of PAH drugs for other forms of PH outside expert centres is discouraged.

The pathology, pathophysiology, and epidemiology of PH due to left heart disease have been discussed previously. PH carries a poor prognosis for patients with chronic heart failure. In one study the mortality rate after 28 months of follow-up was 57% in patients with moderate PH compared with 17% in patients without PH. In addition, patients who have a PVR exceeding 6–8 Wood units (480–640 dynes.s.cm⁻⁵) have an increased risk of post-operative RV failure following heart transplantation.

9.1 Diagnosis

The diagnostic approach to PH due to left heart disease is similar to that for PAH. Doppler echocardiography being the best tool for screening purposes. LV diastolic dysfunction should be suspected in the presence of a dilated left atrium, atrial fibrillation, characteristic changes in mitral flow profile, pulmonary venous flow profile, and mitral annulus tissue Doppler signals and LV hypertrophy. Data on tissue Doppler assessment show that the ratio E/E’ of early mitral valve flow velocity (E) divided by the early diastolic (E’) lengthening velocities correlates closely with LV filling pressures:

when the ratio \( E/E' \) exceeds 15, LV filling pressures are elevated and when the ratio is lower than 8, LV filling pressures are low; if \( 15 > E/E' > 8 \), additional non-invasive investigations are required.\(^2\) Characteristic clinical and echocardiographic features of PH associated with LV diastolic dysfunction are listed in Table 30.\(^3\)

Although increased left-sided filling pressures can be estimated by Doppler echocardiography,\(^3,4,228\) invasive measurements of PWP or LV end-diastolic pressure may be necessary to confirm the diagnosis of PH due to left heart disease (see also section 7.1.11).\(^4\) PWP and LV end-diastolic pressure can be ‘pseudo-normal’, especially when patients have been treated with diuretics. In this setting, exercise haemodynamics volume challenge has been proposed to identify LV dysfunction, but these diagnostic tools require further standardization. An elevated transpulmonary gradient (mean PAP minus mean PWP) \( >12 \text{mmHg} \) is suggestive of intrinsic changes in the pulmonary circulation over-riding the passive increase in PWP. In some patients, it may be difficult to distinguish PAH from PH associated with LV dysfunction especially in patients with borderline values of PWP (15–18 mmHg).

The usefulness of BNP plasma levels for the diagnosis of left heart disease in the presence of PH is not well established because BNP elevations can be observed in both pathophysiological conditions. The value of performing a haemodynamic evaluation with exercise or fluid challenge is also not well established.

The role, significance, and setting of pharmacological testing remain unclear in PH due to left heart disease, although it is recommended in heart transplant candidates to identify patients at higher risk of acute post-operative RV failure.\(^2\) In heart transplant candidates, a persistent increase in PVR \( >2.5 \text{Wood units and/or TPG} > 15 \text{mmHg} \) are associated with up to a 3-fold increase in risk of RV failure and early post-transplant mortality.\(^2,3\) When the PVR can be lowered pharmacologically (e.g. with i.v. nitroprusside) this risk may be reduced.\(^2\) The absence of consensus on a standardized protocol leads to the use of various agents for testing the responsiveness of the pulmonary circulation, including inotropic agents, vasodilators, prostanoids, NO, and phosphodiesterase type-5 inhibitors. Acute post-operative RV failure may also be observed in patients with normal baseline pulmonary haemodynamics, suggesting that other mechanisms may be involved.

### 9.2 Therapy

Currently, there is no specific therapy for PH due to left heart disease. A number of drugs (including diuretics, nitrates, hydralazine, ACE inhibitors, \( \beta \)-adrenoceptor blockers, nesiritide, and inotropic agents) or interventions (LV assist device implantation, valvular surgery, resynchronization therapy, and heart transplantation) may lower PAP more or less rapidly through a drop in left-sided filling pressures.\(^1\) Therefore, management of PH due to left heart disease should be aimed at the optimal treatment of the underlying disease. No heart failure drugs are contraindicated because of PH.\(^2,226\) Few studies have examined the role of drugs currently recommended in PAH. RCTs evaluating the effects of chronic use of epoprostenol\(^222\) and bosentan\(^233,234\) in advanced heart failure have been terminated early due to an increased rate of events in the investigational drug-treated group compared with conventional therapy. A small sized study recently suggested that sildenafil may improve exercise capacity and quality of life in patients with PH due to left heart disease.\(^2,226\) The history of medical therapy for heart failure is full of examples where drugs had positive effects on surrogate endpoints but eventually turned

out to be detrimental, such as the phosphodiesterase type-3 inhibitors. Thus, the use of PAH-specific drugs is not recommended until robust data from long-term studies are available, in particular in ‘out of proportion’ PH associated with left heart disease (Table 3). A sustained reduction of PH is expected in weeks to months in most patients successfully operated for mitral valve disease even if PH represents a risk factor for surgery.33,236

Recommendations for PH due to left heart disease are summarized in the Table 31.

10. Pulmonary hypertension due to lung diseases and/or hypoxia (group 3)

The pathology, pathophysiology, and epidemiology of these conditions have been discussed previously. In COPD, the presence of PH is associated with shorter survival237 and frequent episodes of exacerbation.238 PH is a poor prognostic factor in interstitial lung diseases and PAP is the most important predictor of mortality.37

10.1 Diagnosis

Clinical symptoms and physical signs of PH may be difficult to identify in patients with respiratory disorders. In addition, in COPD, peripheral oedema may not be a sign of RV failure, because it may result from the effects of hypoxaemia and hypercapnia on the renin–angiotensin–aldosterone system. Furthermore, concomitant left heart disease, which is commonly associated with chronic respiratory diseases, may also contribute to raise PAP.

As in other forms of PH, echocardiography is the best screening tool for the assessment of PH. Nevertheless, its diagnostic value in advanced respiratory diseases is lower than in PAH. Reliable assessment of systolic PAP is only feasible in a limited number of cases; estimation of systolic PAP may be inaccurate. The specificity of systolic PAP in detecting PH is low, although the negative predictive value is acceptable.239,240 Indications for echocardiography for the screening of PH in COPD and interstitial lung diseases include: (i) exclusion of significant PH; (ii) evaluation of concomitant left heart disease; and (iii) selection of patients for RHC.

A definite diagnosis of PH relies on measurements obtained at RHC. The indication for RHC in advanced lung disease are: (i) proper diagnosis of PH in candidates for surgical treatments (transplantation, lung volume reduction); (ii) suspected ‘out of proportion’ PH potentially amenable to be enrolled in an RCT with specific PAH drug therapy; (iii) frequent episodes of RV failure; and (iv) inconclusive echocardiographic study in cases with a high level of suspicion.

10.2 Therapy

Currently there is no specific therapy for PH associated with COPD or interstitial lung diseases. Long-term O2 administration has been shown partially to reduce the progression of PH in COPD. Nevertheless, with this treatment PAP rarely returns to normal values and the structural abnormalities of pulmonary vessels remain unaltered.112 In interstitial lung diseases, the role of long-term O2 therapy in PH progression is less clear. Treatment with conventional vasodilators is not recommended because they may impair gas exchange due to the inhibition of hypoxic pulmonary vasoconstriction241,242 and their lack of efficacy after long-term use.243,244 Published experience with specific PAH drug therapy is scarce and consists of the assessment of acute effects245,246 and uncontrolled studies in small series.247–251

The treatment of choice for patients with COPD or interstitial lung diseases and associated PH who are hypoxaemic is long-term O2 therapy. Patients with ‘out of proportion’ PH due to lung diseases (characterized by dyspnoea insufficiently explained by lung mechanical disturbances and mean PAP >40–45 mmHg at rest) should be referred to expert centres and enrolled in clinical trials targeting PAH-specific drug therapy. The use of targeted PAH therapy in patients with COPD or interstitial lung diseases and mean PAP <40 mmHg is currently discouraged because there are no systematic data regarding its safety or efficacy.

Recommendations for PH due to lung diseases are summarized in the Table 32.

11. Chronic thromboembolic pulmonary hypertension (group 4)

The pathology, pathophysiology, and epidemiology of this condition have been discussed above. CTEPH is one of the most prevalent forms of PH. Nevertheless, it is almost impossible to determine the overall prevalence of CTEPH since not all of these patients have a history of acute pulmonary embolism. While acute pulmonary embolism may be clinically silent,252 there is accumulating evidence that CTEPH may also develop in the absence of previous pulmonary embolism.40 In these cases, the disease is probably initiated by thrombotic or inflammatory lesions in the pulmonary vasculature. Once vessel obliteration is
sufficient to cause increases in the PAP, a process of pulmonary vascular remodelling is started which self-perpetuates the progression of PH, even in the absence of further thromboembolic events.253 Certain conditions are associated with an increased risk of CTEPH, including previous splenectomy, the presence of a ventriculo-atrial shunt for the treatment of hydrocephalus, myeloproliferative disorders, and chronic inflammatory bowel diseases. The mechanisms linking these conditions to CTEPH have not been fully explored, but chronic inflammation or chronic bloodstream infection may play a critical role.254

11.1 Diagnosis
Any patient with unexplained PH should be evaluated for the presence of CTEPH. Suspicion should be high when the patient presents with a history of previous venous thromboembolism. Survivors of acute pulmonary embolism should be followed after the acute episode to detect signs or symptoms of CTEPH. Patients with acute pulmonary embolism showing signs of PH or RV dysfunction at any time during their hospital stay should receive a follow-up echocardiography after discharge (usually after 3–6 months) to determine whether or not PH has resolved.

In patients with unexplained PH, a ventilation/perfusion lung scan is recommended to exclude CTEPH. A normal ventilation/perfusion scan rules out CTEPH. Multidetector CT angiography is indicated when the ventilation/perfusion lung scan is indeterminate or reveals perfusion defects. Even in the era of modern multidetector CT scanners, there is not yet enough evidence to suggest that a normal CT angiography excludes the presence of operable CTEPH. Once ventilation/perfusion scanning and/or CT angiogram show signs compatible with CTEPH, the patient should be referred to a centre with expertise in the medical and surgical management of these patients. To determine the appropriate therapeutic strategy, invasive tools including RHC and traditional pulmonary angiography are usually required. Coronary angiography is indicated in candidates for PEA and risk factors for coronary artery disease. In order to minimize risks and repeated procedures these investigations should be performed at the expert centre rather than at the referring hospitals.63 The final diagnosis of CTEPH is based on the presence of pre-capillary PH (mean PAP >25 mmHg, PWP ≤15 mmHg, PVR >2 Wood units) in patients with multiple chronic/organized occlusive thrombi/emboli in the elastic pulmonary arteries (main, lobar, segmental, subsegmental).

11.2 Therapy
Patients with CTEPH should receive life-long anticoagulation, usually with vitamin K antagonists adjusted to a target INR between 2.0 and 3.0.

The decision on how to treat patients with CTEPH should be made at an experienced centre based upon interdisciplinary discussion among internists, radiologists, and expert surgeons. PEA is the treatment of choice for patients with CTEPH as it is a potentially curative option. As a rule, a patient should not be considered inoperable as long as the case has not been reviewed by an experienced surgeon. Detailed pre-operative patient evaluation and selection, surgical technique and experience, and meticulous post-operative management are essential prerequisites for success after this intervention.55 The selection of patients for surgery depends on the extent and location of the organized thrombi in relation to the degree of PH and taking into consideration age and co-morbidities. Proximal organized thrombi represent the ideal indication, while more distal obstructions may prevent a successful procedure. After an effective intervention, a dramatic drop of PVR can be expected with a near normalization of pulmonary haemodynamics. A centre can be considered to have sufficient expertise in this field if it performs at least 20 PEA operations per year with a mortality rate <10%.

Specific PAH drug therapy may play a role in selected CTEPH patients, mainly for three different scenarios: (i) if patients are not considered candidates for surgery; (ii) if pre-operative treatment is deemed appropriate to improve haemodynamics; and (iii) if patients present with symptomatic residual/recurrent PH after pulmonary endarterectomy surgery. Several uncontrolled clinical studies suggest that prostanoids, ERAs, and phosphodiesterase type-5 inhibitors may exert haemodynamic and clinical benefits in patients with CTEPH, regardless of whether these patients were considered operable or inoperable.255–260 The only randomized, placebo-controlled clinical trial that has so far addressed the safety and efficacy of medical treatment was the BENEFIT study, which investigated the effects of bosentan in patients with inoperable CTEPH for a 16-week period.261 This study revealed a significant drop in PVR in the bosentan group but no change in 6MWT, functional class, or time to clinical worsening.

bLevel of evidence.
Given these limited data, further studies are necessary to obtain reliable long-term data on the effects of medical therapies in patients with CTEPH, and these patients should be treated within clinical trials whenever possible. For the present time, no medical therapy has been approved in Europe or the USA for CTEPH. Bilateral lung transplantation is an option for advanced cases that are not suited for PEA.

Recommendations for PH due to CTEPH are summarized in the Table 33.

12. Definition of a pulmonary arterial hypertension referral centre

The purpose of a referral centre is to undertake assessment and investigation of all causes of PH, routinely manage appropriate patients with PAH-specific drug therapy, work with other healthcare providers to obtain best outcomes for patients, and undertake audit, research, and education. Since, in general, centres with a high volume of patients tend to obtain best outcomes, referral centres will need to have sufficient patients on chronic therapy and new referrals to warrant this status. A referral centre should follow at least 50 patients with PAH or CTEPH and should receive at least two new referrals per month with documented PAH or CTEPH. These figures can be adapted according to specific country characteristics (population distribution, geographical constraints, etc.).

Facilities and skills in a referral centre: 180

(1) Referral centres will provide care by a multiprofessional team, which should as a minimum comprise:
- Two consultant physicians (normally from either or both of cardiology and respiratory medicine) with a special interest in PH
- Clinical nurse specialist
- Radiologist with expertise in PH imaging
- Cardiologist with expertise in echocardiography
- Access to psychological and social work support
- Appropriate on-call cover and expertise.

(2) Referral centres will have the following facilities:
- A ward where staff have special expertise in PH
- An intensive therapy unit with relevant expertise
- A specialist outpatient service
- Emergency care
- Diagnostic investigations including echocardiography, CT scanning, nuclear scanning, magnetic resonance imaging, ultrasound, exercise testing, lung function testing, and catheterization laboratory (with expertise in performing vasoreactivity tests)

Level of evidence.

- Access to the full range of specific PAH drug therapy in their country.

(3) There will be established links (e.g. referral criteria, patient pathway, and clinical management protocols) to other services, which may not necessarily be on the same site:
- Genetics service (for research purposes)
- CTD service
- Family planning service
- PEA service
- Lung transplantation services
- Adult congenital heart disease service.

(4) Referral centres are required to undertake a programme of clinical audit of outcomes, which will include survival analysis.

(5) Referral centres will participate in collaborative clinical research in PAH, which includes phase II and phase III clinical trials.

(6) Referral centres will provide regular education about all clinical aspects of PH to appropriate healthcare professionals.

(7) Referral centres will have a link to their national and/or European pulmonary hypertension patients association.

Recommendations for a PH referral centre are summarized in the Table 34.
